Only one trial [57] mentioned topical 5-fluorouracil side effects. Eleven cases of fingertip or periungual warts had nail separation after topical 5-fluorouracil treatment; the rate was 22.9% out of 48 cases in total. However, the nature and proportion of the side effects of the treatment were not elaborated.

### **Comments**

Methodological and statistical heterogeneity (different outcomes, trial periods, units of analysis, vehicles, and concentrations) make it impossible to organize the data from these trials.

## **Localized heat therapy**

### **Efficacy**

#### **Localized heat therapy versus placebo**

Two RCTs [58,59] compared localized heat therapy with placebo; because of heterogeneity in methodology and design, the two trials

are described separately. One trial [58] including 13 patients (29 warts) used local hyperthermia at 50°C lasting 30 min. The cure rates were 86% (25/29) in the treatment group and 41% (7/17) in the control group, the difference was statistically significant (RR, 8.93; 95% CI, 2.14–37.34). Another RCT [59] used local hyperthermia at 44° lasting 30 min once a day for three consecutive days. Two weeks later, patients received similar treatments for two consecutive days. Patients in the control group received a red spot on the targeted lesion without experiencing a heating sensation. Three months later, the cure rates were 53.57% (15/28) and 11.54% (3/26), respectively. The difference was statistically significant (RR, 8.85; 95% CI, 2.15–36.37).

### Drawbacks

One trial [59] showed that 80% of patients (12/15) in the treatment group who had initial complaints of load-bearing pain reported a decreased sensation of pain, one experienced an increased sensation of pain, and two remained stable. In the control group, 14.3% of patients (2/14) reported a decreased sensation of pain, five experienced an increased sensation of pain, and three remained stable. There was a significant difference between the two groups (RR, 24; 95% CI, 3.38–170.38).

### Comments

Methodological and statistical heterogeneity (different outcomes, trial periods, units of analysis, vehicles, and concentrations) make it impossible to organize the data from these trials.

## Light and laser treatment

### Efficacy

#### *Intense pulsed light*

In one trial [60], 79 patients with recalcitrant hand and foot warts were included and randomized into treatments with either paring of warts followed by intense pulsed light (IPL) or paring of warts alone. No significant difference in cure rate was found between the two intervention groups, but the pain intensity after paring plus IPL was significantly higher than that after paring alone.

#### *Pulsed dye laser*

One trial [61] compared the efficacy and safety of pulsed dye laser (PDL) (595 nm PDL + cooling pulses) with a placebo (cooling pulses alone) in the treatment of patients presenting palmoplantar warts. For both groups, hyperkeratosis was removed manually with a scalpel before each session. The results showed that 64% (48/75) of warts in the laser group resolved completely compared with 13% (4/30) in the placebo group ( $P < 0.001$ ). Three trials [62–65] (including adults and children) compared PDL therapy with cryotherapy and no superior efficacy was found (RR, 1.02; 95% CI, 0.85–1.21). One controlled study [66] included 66 lesions from 19 patients. PDL was applied to 33 lesions following 30% SA application twice a day for 5 days; the remaining 33 lesions underwent PDL therapy alone. PDL was administered in both groups at 4-week intervals varying from one to five sessions. Complete clearance was observed after 2.2 sessions in the SA+PDL group versus 3.1 sessions in the PDL group ( $P < 0.05$ ). Although the clearance rate showed no difference between the SA+PDL group and the PDL group after all the sessions, adding SA to PDL decreased the number of sessions to an extent.

#### *Q-switched laser*

Two trials [67,68] (including 212 adults and children with verruca planar) compared Q-switched laser therapy with cryotherapy. All

patients took transfer factor capsules; 92 patients were injected with immunoenhancement for 3 weeks. Q-switched laser therapy obtained higher cure rates (RR, 1.26; 95% CI, 1.12–1.43). The other two trials [69,70] compared Q-switched laser therapy with combination treatments (retinoic acid cream,  $\alpha$ -2b interferon (IFN) ointment, ceramic grinding treatment). The combination treatments were superior to single laser treatment.

#### *CO<sub>2</sub> laser*

Three trials [71–73] (including 453 adults) compared CO<sub>2</sub> laser therapy with cryotherapy. A significant difference was found between the two treatments (RR, 1.36; 95% CI, 1.01–1.83). Two trials [74,75] (including 575 adults) compared CO<sub>2</sub> laser therapy with microwaves therapy. CO<sub>2</sub> laser therapy did not give higher cure rates (RR, 1.05; 95% CI, 0.78–1.41). Another nine trials [64,72,76–82] compared topical treatments ( $\alpha$ -2b IFN ointment, semiconductor laser, different types of CO<sub>2</sub> laser, retinoic acid drugs, etc.) combined with or without CO<sub>2</sub> laser therapy. The results showed that combination treatments were superior to single laser treatment.

#### *Holmium laser*

One trial [83] including 120 children and adult patients with plantar warts compared holmium laser with cryotherapy. The cure rate was 97.5% (78/80) versus 55% (22/40). A significant difference was found between the two treatments, but high risk of bias was found in this trial.

### Drawbacks

Ten RCTs [60,63,65,66,69,76–80] reported the side effects caused by light or laser therapy, including pain, erythema, swelling, hyperpigmentation, burning, itching, desquamation, crusts, and scar. Most of them were mild and tolerable.

### Comments

PDL appears to be an effective treatment in non-genital cutaneous warts, but the efficacy seems to be no superior to that of traditional treatments (cryotherapy). Other laser treatments (Q-switched laser, CO<sub>2</sub> laser, etc.) seem to be more effective than cryotherapy, but more placebo-controlled trials should be undertaken to prove the results. The combination treatment could be considered in clinical practice.

## Imiquimod

### Efficacy

#### *Imiquimod versus retinoic acid drugs*

Four RCTs [84–87] (including 308 adults and children) did this comparison. Topical 5% imiquimod cream did not give higher cure rates (RR, 1.26; 95% CI, 0.98–1.63).

#### *Imiquimod+retinoic acid drugs versus retinoic acid drugs*

Three trials [84,88,89] (including 216 adults and children) did this comparison. The cure rate was 42.99% versus 24.04%. A significant difference was found between the two treatments (RR, 1.80; 95% CI, 1.20–2.70).

#### *Imiquimod+retinoic acid drugs versus imiquimod*

Three trials [84,90,91] (including 229 adults and children) did this comparison. The cure rate was 52.63% versus 22.61%. A significant difference was found between the two treatments (RR, 2.33; 95% CI, 1.59–3.42).

### Other comparisons

Nine trials [92–100] compared topical treatments ( $\alpha$ -2b IFN ointment, traditional Chinese medicine, cryotherapy, microwave, hot water immersion, etc.) with or without imiquimod cream. The limited evidence showed the combination treatments were superior to single treatment.

### Drawbacks

Sixteen RCTs reported the side effects caused by imiquimod cream, including erythema, burning, tingle, swelling, erosion, itching, edema, desquamation, and pigmentation. No systemic side effects were reported.

### Comments

No evidence showed good efficacy of 5% imiquimod cream on non-genital cutaneous warts. Although the pooled data showed combined treatment with retinoic acid drugs to be effective in verruca planar, the results should be verified by high-quality RCTs.

## Retinoic acid drugs

### Efficacy

#### Retinoic acid

*Retinoic acid versus  $\alpha$ -2b interferon* Two RCTs [101,102] (including 218 adults and children) compared retinoic acid ointment with  $\alpha$ -2b IFN ointment. Topical retinoic acid ointment did not give higher cure rates (RR, 0.87; 95% CI, 0.59–1.31).

*Retinoic acid+ $\alpha$ -2b interferon versus retinoic acid* Three RCTs [101–103] (including 324 adults and children) did this comparison. A significant difference was found between the two treatments (RR, 1.99; 95% CI, 1.53–2.57).

*Retinoic acid+ $\alpha$ -2b interferon versus  $\alpha$ -2b interferon* Four RCTs [101,102,104,105] compared retinoic acid cream combined with  $\alpha$ -2b IFN ointment in 350 adults and children. The pooled data showed a significant difference between the two treatments (RR, 1.84; 95% CI, 1.45–2.32).

#### Tazarotene

*Tazarotene+ $\alpha$ -2b interferon versus tazarotene* Two RCTs [106,107] did this comparison in 68 patients with verruca planar and 104 patients with plantar warts. The combination treatment group had a higher cure rate than the tazarotene ointment only group (RR, 2.79; 95% CI, 1.62–4.81).

*Tazarotene+ $\alpha$ -2b interferon versus  $\alpha$ -2b interferon* In one RCT [108], 98 adults and children with verruca planar were randomized into two groups (topical tazarotene cream combined with  $\alpha$ -2b IFN ointment group and topical  $\alpha$ -2b IFN ointment alone group). After 4 weeks, the cure rates were 48.08% (25/52) versus 23.91% (11/46). The former had greater efficacy than the latter on treatment of verruca planar.

*Tazarotene versus ftibamzone* Two RCTs [109,110] (including 347 adults and children with verruca planar) compared tazarotene cream with ftibamzone ointment. The pooled data did not demonstrate a significant difference in cure rates (RR, 1.15; 95% CI, 0.80–1.63).

### Other comparisons

Retinoic acid ointment, tazarotene cream, adapalene gel, and isotretinoin gel were respectively compared with different products

or topical treatments in 16 trials [91,97,111–124], seven trials [84,89,90,125–128], five trials [120,129–132], and one trial [133]. The limited evidence showed that the combination treatments were superior to the single treatment. However, all the trials had a high risk of bias, so the results were less worthy of belief.

### Drawbacks

All RCTs except one trial [120] reported the side effects caused by retinoic acid drugs. The most common drawbacks were erythema, itching, and desquamation. Most patients could get better after treatment cessation, using vitamin E ointment, reducing treatment frequency, or even keeping on treatment. Other side effects were burning, swelling, photosensitive, tight skin, tingling, pigmentation, and so on.

### Comments

It was hard to draw a definite conclusion on the efficacy of retinoic acid drugs because high-quality placebo-controlled trials were absent. Although the pooled data showed that retinoic acid drugs combined with  $\alpha$ -2b IFN treatment were effective in verruca planar, the generally low quality of trials means there are reservations. Furthermore, clinical heterogeneity made it impossible to organize the data from most trials. So there was no compelling evidence to give retinoic acid drugs to non-genital cutaneous warts patients.

## Other local treatments for warts

Intralesional IFN as a treatment for warts is more of historical interest. Six trials [134–139], most dating from the 1970s and 1980s, were found using this treatment; evidence provided by all the trials was severely limited by heterogeneity of the methodology and design, and overall did not suggest any striking efficacy.

In one RCT [140] of intralesional antigen therapy, a form of local immunotherapy was designed to elicit an immune reaction in warts, and patients were injected with *Candida*, *mumps*, or *Trichophyton* antigens. Unfortunately, the design of the trial was made more complex by the addition of intralesional IFN, resulting in four treatment arms (antigen with or without IFN and placebo with or without IFN) rather than two, which would have given much clearer data. Up to five injections were given at 3-weekly intervals into the largest wart in each patient. Blinding involved only the patients and not the investigators, introducing a source of potentially significant bias. The main outcome reported was a reduction of more than 75% in the wart surface area at the end of treatment – an outcome of no relevance to patients (who naturally want their warts cleared). No long-term follow-up appears to have been carried out. A total of 201 patients with refractory warts completed the trial; 57 of 95 patients (60%) injected with antigen with or without additional IFN experienced the resolution of at least one wart, in comparison with 25 of 106 patients (24%) injected with saline or IFN alone. The number of patients who experienced complete clearance of all warts is a little difficult to ascertain from the paper, but it appears to have been 21 of 95 (22%) in the treatment groups and 11 of 106 (10%) in the “placebo” groups. For a fairly painful and expensive treatment, this does not appear to offer any striking advantages.

One RCT [141] compared 20% zinc oxide and 15% SA complex, involving 44 patients who were randomized to the two treatments twice a day for 3 months. The results showed that the cure rates of zinc oxide and SA complex group were respectively 50% and 42%, and there was no statistically difference between the two treatments (RR, 1.44; 95% CI, 0.44–4.76). Topical zinc oxide is a possible treatment of warts, but needs more RCTs to support.

One RCT [142] compared topical  $\alpha$ -lactalbumin-oleic acid with placebo. The trial employed an unusual hybrid molecule (consisting of a combination of  $\alpha$ -lactalbumin from human breast milk and oleic acid), which was said to be lethal to a wide range of transformed cells but harmless to normal ones. The trial was properly randomized and double blinded, and the analysis focused on the main outcome of a more than 75% reduction in wart volume, rather than the more relevant complete clearance of warts. Unfortunately, the trial defaulted to an open-label design after 3 months, making the long-term follow-up data unconvincing. Although 100% of patients in the treatment group were reported to have experienced a reduction in wart volume of more than 75%, only 21% of the lesions in the treatment group resolved completely. Nine of 20 patients (45%) with active treatment experienced the resolution of at least one wart, in comparison with three of 20 (15%) in the placebo group (RR, 3.0; 95% CI, 0.95–9.48). Given the size of the trial, and consequently the wide CIs, the results were unconvincing.

One RCT [143] compared smoke from leaves of *Populus euphratica* Olivier and conventional cryotherapy, once a week, for 10 times. After 22 weeks, the cure rates were 68% (16/24) and 46% (13/28) respectively (RR, 2.31; 95% CI, 0.75–17.13).

No RCTs were identified that studied the efficacy of the following treatments: surgical excision, curettage and cautery, formaldehyde, podophyllin, and podophyllotoxin.

### Key points

- Topical preparations containing SA are generally effective and safe for treating warts.
- The available, rather limited, evidence shows that no significant difference was seen between cryotherapy and topical treatments containing SA.
- Contact immunotherapy with DNCB appears to be a promising treatment, but is probably best reserved for highly refractory warts.
- PDT and PDL therapy do not appear to have any particular advantage in terms of higher cure rates or fewer adverse effects than the other simpler and cheaper local treatments available.
- There is no compelling evidence for the efficacy of intralesional bleomycin.

# Molluscum contagiosum

Minh L. Lam

Dermatology Department, Queen's Medical Centre, Nottingham, UK

## Background

### Definition

Molluscum contagiosum is a benign infection of the skin and mucous membranes caused by the molluscum contagiosum pox virus. Most people with mollusca have multiple lesions, which typically begin as small papules that enlarge to around 3–6 mm and rarely to more than 1 cm in diameter. Fully developed papules typically have a central umbilication or depression that contains a white, waxy, curd-like core. Most lesions resolve without scarring, but they may cause discomfort and/or itching (Figure 39.1) [1]. Mollusca can be associated with a surrounding dermatitis and occasionally a reactive skin eruption similar to Gianotti–Crosti syndrome [2].

### Incidence

Infections with the molluscum contagiosum virus occur throughout the world, but the incidence varies considerably, with higher rates in areas with warm climates [1]. Children are most often affected [3–5]. In a British study, the incidence was 243 per 100 000 person-years (py) in males and 231 per 100 000 py in females. Ninety percent of cases were reported in children aged 0–14 years (incidence 1265 per 100 000 py) [4]. In New Guinea, the annual attack rate was 6% in children aged 0–9 years [6]. Incidence rates are higher in American Indians and Alaska Natives than in the general US population [7]. Patients with weakened immune system are particularly prone to molluscum infection and have increased difficulty in clearing lesions (point prevalence in patients with human immunodeficiency virus/acquired immune deficiency syndrome (AIDS): 5–18%) [8–11]. A history of eczema was found in 62% of children with molluscum contagiosum in Australia [12]. Another Japanese study found that lifetime molluscum was increased in young children with atopic eczema [13].

### Etiology

Molluscum contagiosum, also known as *Molluscipoxvirus*, is a member of the pox virus (Poxviridae) family [14,15]. Transmission of molluscum occurs during contact with infected lesions, contami-

nated fomites, or sexual contact [16]. Autoinoculation through scratching is also suspected, especially as lesions can develop along scratchmarks (koebnerization) [17]. Outbreaks have occurred among children attending swimming pools [18,19].

### Prognosis

After a variable incubation period (2–6 months), the lesions usually persist for several months and resolve as a result of an inflammatory response which may develop spontaneously, following trauma (e.g., scratching) or secondary bacterial infection [1,20,21]. In immunocompromised people – for example, patients with AIDS – molluscum contagiosum usually does not resolve spontaneously and is often refractory to treatment [1,22].

### Aims of treatment

Molluscum contagiosum is self-limiting in immunocompetent individuals. Many parents of children with molluscum may seek treatment because of concerns about the appearance of the lesions, lesions becoming sore due to friction from clothing and in skin folds, persistence of lesions, spread of lesions, concern about secondary infection, or because of other people's comments. The aims of treatment are to shorten the duration of the condition, to resolve discomfort (e.g., itching), to limit spread, and to prevent secondary bacterial infection [1].

### Relevant outcomes

Clinical cure of all infected lesions is the clinically most relevant outcome. Treatment success is defined as the proportion of patients completely cleared of all molluscum contagiosum lesions. Treatment success should ideally be assessed 4–8 weeks after the discontinuation of treatment because of the tendency of molluscum to heal spontaneously in healthy children. Secondary outcomes include the time to clearance of all lesions and the cosmetic result.

### Methods of search

We included randomized controlled trials (RCTs) of all interventions for cutaneous, nongenital infection with molluscum contagiosum in immunocompetent patients. We updated the previous

Figure 39.1 Molluscum contagiosum.

edition's chapter by searching the Cochrane Controlled Trials Register (May 2013), the Cochrane Library for systematic reviews (May 2013), and Medline (June 2006–May 30, 2013).

## Question

**In immunocompetent patients with cutaneous, nongenital molluscum contagiosum, what is the efficacy (defined as the proportion of patients completely cleared of all lesions at 4–8 weeks after discontinuation of treatment) of physical destructive methods, topical and systemic treatments, or waiting for spontaneous resolution?**

### Evidence summary

A Cochrane review on the interventions for cutaneous molluscum contagiosum was published in 2006 and subsequently updated to include studies published up to June 2009 [23]. Only 11 studies, with a total number of 495 participants, could be analysed. Study limitations included no blinding (four studies), high drop-out rates (three studies), and no intention-to-treat analysis, and the small study sizes meant inadequate power to detect possible important differences. The overall conclusion from the authors was that no single intervention has been shown to be convincingly effective in the treatment of molluscum contagiosum [23].

We identified another seven relevant studies, including two of the largest RCTs ever conducted in the intervention of molluscum contagiosum. These two studies, identified by Katz and Swetman [24], suggest that imiquimod 5% is no more effective than placebo in achieving clearance of mollusca, yet these studies have never been published in a peer-reviewed journal [25]. A study by Mutairi *et al.* comparing 5% imiquimod cream with cryotherapy is the only

RCT we have identified that provides supporting evidence for a physical destructive method in the treatment of molluscum contagiosum [26]. The clearance rate of 100% (37 out of 37 subjects) was the highest out of all studies, though clearly tolerability and scarring are major drawbacks. This study also found a 92% (34/37) clearance rate with imiquimod after 16 weeks, in contrast to the previously discussed Papadopoulos studies [25], which found clearance rates of 24% (112/470 – pooled data) after 18 weeks.

Cantharidin, a blister beetle extract, has been widely used to treat viral warts as well as molluscum contagiosum. However, the only RCT we found for the treatment of mollusca suggests that there was no significant improvement compared with placebo, though it was a small study that may have been underpowered [27].

Despite previous studies suggesting no benefit in treating mollusca with potassium hydroxide compared with placebo [28, 29], there have been two further studies published, by Rajouria *et al.* [30] and Uçmak *et al.* [31], showing a greater reduction in mean lesion count and improved complete clearance with potassium hydroxide. However, in both studies, patient numbers were small and no control groups were present.

## Sodium nitrite

### Efficacy

After 3 months of treatment with sodium nitrite 5%–salicylic acid 5% cream with occlusion on each lesion overnight, 75% of patients (12/16) completely cleared, in comparison with 25% of children (4/16) treated with salicylic acid 5% cream [32].

### Drawbacks

Brown staining of the skin was recorded in six patients out of 16 with active treatment, but in none in the control group. The treatment is awkward and time consuming, and causes irritation in some patients (frequency not reported) [32].

### Comment

Because of potential staining, sodium nitrite is not recommended for facial molluscum contagiosum. It appears to be beneficial for lesions on the trunk, although larger trials are needed to confirm the results.

## Salicylic acid, phenol

### Efficacy

Salicylic acid 12%, lactic acid 4% gel (Salatac) applied once to twice weekly, and 10% phenol in a 70% alcohol solution applied once daily had similar clearance rates to those of the vehicle (Salatac 57% (21/37) versus phenol 42% (17/41) versus placebo 44% (16/36); completely cleared,  $P = 0.38$ ) [33].

### Drawbacks

Significantly more patients discontinued treatment due to stinging in the salicylic acid group in comparison with phenol and vehicle. No serious adverse events occurred [33].

### Comment

Because an efficacy greater than that of the vehicle was not demonstrated in this study, neither salicylic acid nor phenol are recommended. The sample size of the study was quite small, and important treatment differences might have been missed. In contrast to the full-text paper, in which the results were based on an intention-to-treat analysis, the authors reported results after excluding drop-outs in a previously published abstract. Salicylic acid appears to be ben-

eficial in the per-protocol analysis, highlighting the potential of misleading inferences due to inappropriate statistical methods [33,34].

### Imiquimod versus vehicle and cryotherapy

#### Efficacy

Theos *et al.* found imiquimod 5% cream applied three times a week for 12 weeks was not superior to the vehicle in inducing complete clearance (imiquimod 33.3% completely cleared (4/12) versus vehicle 9.1% (1/12);  $P = 0.32$ ); partial responses (defined as at least a 30% reduction in the lesion count) were more frequent in patients treated with imiquimod [35]. An RCT by Al Mutairi *et al.* demonstrated imiquimod 5% cream applied five times a week led to complete cure at 16 weeks in 34/37 participants (22/37 at week 6), compared with complete clearance in all 37 patients receiving once-weekly cryotherapy after 3 weeks [26]. Interestingly, a commentary by Katz and Swetman [24] in 2013 on the deficiencies of US law in failing to mandate that important negative studies are published in full in peer-reviewed journals highlighted two unpublished RCTs (by Papadopoulos in 2006) conducted in comparing imiquimod 5% used three times weekly for up to 16 weeks against placebo [25]. Both studies found no statistical difference in complete clearance rates of those treated with imiquimod, 52/217 and 60/253 (both 24%) compared with placebo, 60/253 and 35/216 (24% and 16%).

#### Drawbacks

Tolerability did not differ significantly between imiquimod and the vehicle in the study by Theos *et al.* with local skin reactions and pruritus commonly reported in both groups [35]. The Al Mutairi *et al.* study showed significantly more adverse effects with cryotherapy compared with imiquimod, including blistering (9/37), pigmentary changes (15/37), and scarring (8/37). Together with the treatment-associated pain of cryotherapy, this represents a major drawback of the use of this modality in young children. Pain during application (27/37) and erythema (28/37) were also common side effects reported with imiquimod [26]. A pharmacokinetic study suggested that percutaneous absorption in imiquimod was low; however, leukopenia and neutropenia were commonly noted [36].

#### Comment

With a total of 23 participants included, the first study was not sufficiently powered to show small differences [35]. The Al Mutairi *et al.* study reported high clearance at 16 weeks, for both imiquimod and cryotherapy, but given the self-limiting nature of molluscum, the lack of a placebo arm in this trial was a significant flaw, as was the lack of description of method of randomization and subsequent allocation concealment and blinding. The unpublished trials cited by Katz and Swetman highlight the problem of publication bias against studies with negative results. The original manufacturer of imiquimod and clinicians involved in their pivotal studies chose not to publish the results of these studies in a journal, yet they are available on the US Foods and Drugs Administration (FDA) website. As a result, these key studies have not been picked up and included in dermatology textbooks, reference guides, and even the Cochrane review on the interventions for cutaneous molluscum contagiosum.

### Australian lemon myrtle (*Backhousia citriodora*)

#### Efficacy

The essential oil of the Australian lemon myrtle (*Backhousia citriodora*) (Herbal BioScience, Oakvale, California, USA), applied once

daily for 21 days, induced partial remission (defined as at least a 90% reduction in the lesion count) in 56% (9/16) of patients, in comparison with 0% (0/15) treated with the vehicle. Complete response rates are not reported [37].

#### Drawbacks

None. The treatment was well tolerated in the study [37].

#### Comment

Australian lemon myrtle appears to be beneficial against molluscum contagiosum. However, complete response rates are not reported, and complete clearance is probably of most relevance for the patient [37]. Further evidence has suggested cytotoxic effects associated with the use of this oil [38,39], which has led the research group (Centre for Biomedical Research Inc.) to evaluate another formulation of lemon myrtle to improve safety and efficacy [40].

### Combination of essential oil of *Melaleuca alternifolia* with iodine

#### Efficacy

The same company that evaluated *Backhousia citriodora* went on to test another essential plant oil obtained from *Melaleuca alternifolia*, more widely known as tea tree oil. They compared melaleuca oil against melaleuca plus iodine versus iodine alone in a three-armed RCT of 53 children and found that 16 out of 19 children (84%) had a greater than 90% reduction of lesions in the combination group, compared with one out of 16 (6%) and three out of 18 (17%) for the iodine and melaleuca-only groups ( $P < 0.01$ ) by the end of day 30 using an intention-to-treat analysis [40]. Complete response rates are not reported.

#### Drawbacks

Adverse effects were limited to application site redness that did not result in any children withdrawing from the study. Long-term scarring after resolution of the lesions was not assessed.

#### Comment

This study suggests that a specially formulated combination of tea tree oil and iodine is more effective than either product used alone, although the absence of a vehicle-only group is a limitation given the tendency of molluscum to resolve spontaneously. The internal validity of this company-sponsored trial is questionable given that the method of randomization and subsequent allocation concealment is not described, and although parents and the evaluating physicians were reported to have been blinded to the treatment allocation, it is unclear whether assessment was truly blinded given that iodine stains the skin. Plant extracts could have a beneficial effect in inducing local clearance of mollusca, and an independent trial of tea tree oil plus iodine versus a vehicle of similar colour and smell with blinded assessment of complete clinical response might be worthwhile.

### Povidone iodine solution combined with salicylic acid plaster

#### Efficacy

Ohkuma found that 10% povidone iodine solution and 50% salicylic acid plaster was effective in curing 20/20 participants (100%) compared with 3/5 who received povidone iodine alone (60%) and 7/10 who received salicylic acid plaster alone (70%). Thus, the combination treatment cured more participants than either component alone (and more rapidly – 26 days, 86 days, and 47 days were mean

time to cure for each group respectively), though this failed to reach statistical significance [41].

### Drawbacks

All participants developed local redness within 3–7 days of starting treatment. The duration of redness was variable, and the more marked the inflammation the earlier the cure was [41].

### Comment

Based on the small number in the comparator groups and lack of statistical difference between the groups there is insufficient evidence to recommend this treatment.

## Benzoyl peroxide

### Efficacy

In total, 73% (11/15) of patients treated with benzoyl peroxide 10% cream twice daily for a total of 4 weeks had complete remission of all lesions at week 6, in comparison with 33% (5/15) of patients treated with tretinoin 0.05% cream (relative risk [RR], 2.20; 95% confidence interval [CI], 1.01–4.79;  $P = 0.05$ ) [42].

### Drawbacks

Side effects were limited to mild dermatitis in both treatment groups (exact numbers not reported) [42].

### Comment

Benzoyl peroxide 10% cream appears to be beneficial for molluscum contagiosum. However, owing to poor reporting quality and methodological shortcomings (i.e., failure to carry out an intention-to-treat analysis) bias cannot be ruled out [42], and better studies are needed.

## Cantharidin versus placebo

### Efficacy

Cantharidin is a topical vesicant that has been used to treat molluscum for several decades. It is an extraction from blister beetles, *Cantharis vesicatoria*, and when applied to the skin it produces a small intraepidermal blister that usually heals without scarring. In this randomized double-blind study, 15% (2/13) of those who received cantharidin and 6% (1/16) of those who received vehicle achieved complete clearance after 8 weeks, which was not statistically different [27].

### Drawbacks

Although the placebo vehicle had an identical texture and smell to the active drug, there were significant differences in reported adverse effects in that blistering was reported in 12/13 of those who received cantharidin, but in only 8/16 receiving placebo. The active group also experienced more pigmentary changes (6/13 vs 0/16). Three patients in the cantharidin group were excluded because they were later found not to meet the inclusion criteria [27].

### Comment

Despite anecdotal evidence supporting the use of cantharidin, this study is the first prospective, placebo-controlled, randomized trial evaluating the safety and efficacy of cantharidin for molluscum contagiosum. Although the performance of cantharidin was similar to that of placebo in this study, it was probably too small to be conclusive.

## Potassium hydroxide versus saline and tretinoin cream

### Efficacy

Bazza and Ryatt reported a study where treatments were randomized to the right or left side of the body. Application of 5% potassium hydroxide was compared with 0.9% saline. In both groups, 85% (17/20) of patients were cured at 12 weeks [28]. The same comparison was made by Short *et al.*, where treatment with 10% potassium hydroxide was successful after 3 months in 70% (7/10) compared with 20% (2/10) in the saline group [29]. Pooling these data showed no significant benefit from potassium hydroxide. Rajouria *et al.* compared 5% potassium hydroxide with tretinoin 0.05% cream in a nonrandomized controlled study, with 25 patients allocated to each treatment, and found at 4 weeks a mean reduction in lesion count from 9.48 ( $\pm 3.00$  standard deviation [SD]) to 1.67 ( $\pm 0.58$  SD) and from 8.35 ( $\pm 2.82$  SD) to 2.00 ( $\pm 1.00$  SD) for potassium hydroxide and tretinoin respectively [30]. A study by Uçmak *et al.* compared treatment with potassium hydroxide at concentrations of 2.5% and 5%. Complete clearance was reported in 23% (3/13) and 67% (8/12) at 60 days after commencing treatment with potassium hydroxide twice daily in each group respectively [31].

### Drawbacks

Four patients (two in each group) dropped out of the Rajouria *et al.* study due to noncompliance, and a table of side effects for the remainder of the participants showed erythema (14/23), edema (5/23), and burning (4/23) reported in those treated with 5% potassium hydroxide, though erosions (6/23) and ulceration (1/23) were also reported. Side effects from potassium hydroxide were common in the study by Uçmak *et al.*, with at least one side effect reported in 86.4% and 91.7% of those treated with 2.5% and 5% potassium hydroxide respectively. The exact number and nature of side effects were not reported. Tretinoin 0.05% cream appeared to produce milder adverse effects.

### Comment

The studies by Bazza and Ryatt and by Short *et al.* showed no significant benefit of potassium hydroxide in clearing molluscum. The Rajouria *et al.* study focused on a reduction in lesion count rather than clearance at 4 weeks. Although there was a significant reduction in mean lesion count with both treatments, there was no significant difference between the treatments and no placebo arm to assess the mean reduction in those without any treatment. Therefore, the study suggests potassium hydroxide (and tretinoin cream) improve the resolution of mollusca, but how much better than spontaneous resolution is unclear. This study was also nonblinded and nonrandomized, which is at high risk of selection and information bias, and it is unclear whether an intention-to-treat analysis was performed. Although the Uçmak *et al.* study was reported as randomized, allocation concealment was unclear. Despite efforts to blind study participants, it is unclear whether assessors had been blinded, and in fact the same observer was used for all follow-up visits, risking significant information bias. This study would also have benefitted from a control arm.

## Calcarea carbonica

### Efficacy

This homeopathic drug given daily for 15 days resulted in improvement in 93% (13/14) participants in the treatment arm and 17% (1/6) in the placebo arm of the trial (RR, 5.57; 95% CI, 0.93–33.54; not statistically significant) [43].

**Table 39.1** Summary of RCTs identified on molluscum contagiosum in otherwise healthy individuals.

First author, ref.	Intervention	Comparators	Study population	Sample size (n)	Study design	Duration of active treatment	Outcome measures	Main results	Study quality: Randomization <sup>a</sup> Blinding <sup>b</sup> Statistical analysis <sup>c</sup>
Ormerod (1999) [32]	Sodium nitrite 5%–salicylic acid 5% cream	Salicylic acid 5% cream alone	Children (median age 6 years)	32	Double-blind RCT	3 months	Complete clearance rate after 3 months	Sodium nitrite 5%–salicylic acid 5% cream 75% (12/15) vs salicylic acid 5% cream 25% (4/15); completely cleared ( $P = 0.01$ )	Adequate Adequate Inadequate
Leslie (2005) [33]	Salicylic acid 12%, lactic acid 4% gel (Salatac)	(a) 10% phenol in 70% alcohol, (b) 70% alcohol (placebo)	Children (1–15 years)	114	Nonblinded RCT	6 months	Complete clearance rate after 6 months	Salatac 57% (21/37) vs phenol 42% (17/41) vs placebo 44% (16/36); completely cleared ( $P = 0.38$ )	Adequate Not applicable Adequate
Theos (2004) [35]	Imiquimod 5% cream	Vehicle	Children ( $4.7 \pm 1.9$ years)	23	Double-blind RCT	12 weeks	Complete clearance rate at week 12	Imiquimod 33.3% (4/12) vs vehicle 9.1% (1/12); completely cleared ( $P = 0.32$ )	Inadequate Inadequate Adequate
Burke (2004) [37]	Essential oil of Australian lemon myrtle	Vehicle	Children ( $4.6 \pm 3.1$ years)	31	Double-blind RCT	3 weeks	Proportion of patients with reduction of lesions >90%	Essential oil of Australian lemon myrtle 56% (9/16) vs vehicle 0% (0/15); met efficacy outcome ( $P < 0.05$ )	Adequate Adequate Adequate
Saryzadi (2004) [42]	Benzoyl peroxide 10% cream	Tretinoin 0.05% cream	Children (not reported)	30	Investigator-masked RCT	4 weeks	Complete clearance rate at week 6	Benzoyl peroxide 73% (11/15) vs tretinoin 0.05% 33% (5/15); completely cleared ( $P = 0.05$ )	Inadequate Inadequate Inadequate
Antony (2001) [44]	Cimetidine 35 mg/kg/day	Placebo	Children (1–16 years)	38	Double-blind RCT	3 months	Complete clearance rate after 4 months	Cimetidine 50% (4/8) vs placebo 46% (5/11); completely cleared ( $P > 0.05$ )	Inadequate Adequate Inadequate
Markum (2012) [40]	<i>Melaleuca alternifolia</i> + iodine	<i>Melaleuca alternifolia</i> alone Iodine alone	Children ( $6.3 \pm 5.1$ years)	53	3-arm RCT	30 days	Proportion of patients with reduction of lesions >90%	<i>Melaleuca alternifolia</i> +iodine 84% (16/19) vs <i>Melaleuca alternifolia</i> alone 17% (3/18) vs iodine alone 6% (1/16) met efficacy outcome ( $P < 0.01$ )	Inadequate Inadequate Adequate
Al Mutairi (2010) [26]	5% imiquimod cream	Cryotherapy	Children (2–8 years)	74	Nonblinded RCT	16 weeks	Complete clearance rate after 16 weeks	Imiquimod 92% (34/37) vs cryotherapy 100% (37/37) completely cleared ( $P = 0.3$ )	Inadequate Inadequate Adequate
Ohkuma (1990) [41]	10% povidone iodine solution and 50% salicylic acid plaster	10% povidone iodine solution alone, 50% salicylic acid plaster alone	Children (2–9 years)	35	3-arm RCT	Unclear	Complete clearance Time to cure	10% povidone iodine solution and 50% salicylic acid plaster 20/20 completely cleared at 26 days vs 10% povidone iodine solution alone 3/5 at 68 days vs salicylic acid plaster alone 7/10 at 47 days ( $P > 0.05$ )	Inadequate Inadequate Unclear

Bazza (2007) [28]	5% potassium hydroxide	0.9% normal saline	Children (2–12 years)	30	Double-blind RCT	3 weeks	Complete clearance after 12 weeks	5% potassium hydroxide 85% (17/20) vs 0.9% normal saline 85% (17/20) completely cleared	Unclear Adequate Inadequate
Short (2006) [29]	10% potassium hydroxide	Saline	Children (2–12 years)	20	Double-blind RCT	Unclear	Complete clearance up to 90 days	10% potassium hydroxide 70% (7/10) vs saline 20% (2/10) completely cleared (pooled with data above $P > 0.05$ )	Unclear Adequate Unclear
Rajouria (2011) [30]	5% potassium hydroxide	0.05% tretinoin cream	Children (6 months–14 years)	46	Nonrandomized controlled trial	4 weeks	Mean reduction in lesion count after 4 weeks	5% potassium hydroxide: $9.48 \pm 3.00$ SD to $1.67 \pm 0.58$ SD vs 0.05% tretinoin: $8.35 \pm 2.82$ SD to $2.00 \pm 1.00$ SD	Inadequate Inadequate Inadequate
Uçmak (2013) [31]	5% potassium hydroxide	2.5% potassium hydroxide	Children (15 months–18 years)	25	Patient-blinded RCT	60 days	Complete clearance after 60 days	5% potassium hydroxide 67% (8/12) vs 2.5% potassium hydroxide 23% (3/13) completely cured ( $P < 0.047$ )	Inadequate Inadequate Inadequate
Manchanda (1997) [43]	Calcareo carbonica	Placebo	Children and adults (0–30 years)	20	RCT	15 days	Improvement (not clear after what period)	Calcareo carbonica 93% (13/14) vs placebo 17% (1/6) improvement ( $P > 0.05$ )	Inadequate Adequate Inadequate

RCT, randomized controlled trial.

<sup>a</sup>Adequate, if clear description of method of randomization and concealment of allocation of randomization given.<sup>b</sup>Adequate, if assessors and participants were completely blinded to the study interventions.<sup>c</sup>Adequate, if an intention-to-treat analysis was carried out; that is, all patients originally randomized were included in the final main analysis.

**Drawbacks**

The study duration, time to resolution, dosing regimen, and adverse events were not reported and the study was not analyzed by an intention-to-treat principle. The number of dropouts (20/104 for the whole trial, including other skin conditions) is unclear for the molluscum participants.

**Comment**

For the above reasons, calcarea carbonica is not recommended as a treatment for molluscum.

**Cimetidine****Efficacy**

Oral cimetidine 35 mg/kg per day for 3 months added no notable benefit compared with placebo treatment: cimetidine 50% (4/8) versus placebo 46% (5/11), completely cleared after 4 months ( $P > 0.05$ ) [44].

**Drawbacks**

Half of the patients (19 of 38) dropped out. The reasons for withdrawal are not reported [44].

**Comment**

Cimetidine is not recommended in the treatment of molluscum contagiosum.

**Destructive methods such as cryotherapy, electrodesiccation, physical squeezing**

Apart from the Al Mutairi *et al.* study of the trial that compared imiquimod with cryotherapy [26], we were not able to identify any trials demonstrating the efficacy of these commonly used physical destructive treatments against each other or against no treatment. Although this study demonstrated high cure rates within a short period (37/37 completely cleared at 3 weeks), like most destructive methods this benefit must be balanced against tolerability in young children and adverse effects such as scarring.

**Implications for clinical practice**

Molluscum contagiosum is a self-limiting disease in the immunocompetent host. Treatment is not necessary in most cases, since natural resolution occurs. Topical treatments that do not leave scars and are not associated with severe adverse events may be tried in order to limit the spread, shorten the course of the disease, for cosmetic reasons, and/or to suppress accompanying symptoms. The decision to treat must take in to account these issues as well as patient factors, such as a child's age, history of atopy, secondary infection, and so on. It is unclear whether treatment of molluscum-associated dermatitis can limit spread of lesions [2].

Treatment options for mollusca that can be recommended on the basis of the existing scant evidence are 5% sodium nitrite with 5% salicylic acid cream for nonfacial lesions and cryotherapy. Salicylic acid preparations, phenol, cantharidin, imiquimod 5% cream, povidine iodine solution with salicylic acid plaster, oral calcarea carbonica, and cimetidine are not recommended on the basis of the data available. Most studies have small sample sizes and may, therefore, be underpowered to detect differences in clinical outcomes. A summary of trials for the treatment of molluscum contagiosum is presented in Table 39.1.

The evidence base for treatment and prevention of spread of mollusca is very poor considering it is such a common condition.

Future studies need to be much larger, randomized, include blinded assessment of responses, and should be prospectively registered and fully reported. The unit of analysis should be number of people and not numbers of lesions, and placebo or no treatment arms should be included. The importance of publishing studies with negative results should also be emphasized in order to avoid persistent use of treatments that have been proven not to work any better than placebo.

**Key points**

- Molluscum contagiosum in otherwise healthy people is self-limiting.
- Treatment is not necessary in most people.
- Many popular treatments, including physical destruction, have not been evaluated properly with well-designed, prospective, double-blinded randomized control trials.
- Topical sodium nitrite, cryotherapy, and possibly benzoyl peroxide preparations appear to shorten the duration of the disease.
- Current evidence suggests that salicylic acid preparations, phenol, cantharidin, imiquimod, and oral cimetidine are no more effective than placebo.

**Acknowledgments**

I would like to thank Jochen Schmitt and Thomas L. Diepgen, the authors of this chapter in the second edition, for their contribution.

# Impetigo

Sander Koning<sup>1</sup>, Renske van der Sande<sup>1</sup>, Lisette W.A. van Suijlekom-Smit<sup>2</sup>, and Johannes C. van der Wouden<sup>3</sup>

<sup>1</sup>Department of General Practice, Erasmus MC-University Medical Center Rotterdam, Rotterdam, Netherlands

<sup>2</sup>Department of Paediatrics, Erasmus MC-University Medical Center Rotterdam, Rotterdam, Netherlands

<sup>3</sup>Department of General Practice, VU University Medical Center, Amsterdam, Netherlands

## Background

### Definition

Impetigo (Figure 40.1) is a contagious superficial skin infection, characterized by superficial erosions covered with honey-colored crusts, most often on the face. A distinction is made between bullous and nonbullous impetigo. Impetigo may be primary or secondary to other skin diseases, such as atopic eczema.

### Incidence

Impetigo is most frequent in children; the incidence rates peak at 1–8 years of age. Population-based incidence rates are unknown. Impetigo is common in general practice, with incidence rates of around 20 episodes per 1000 children per year seen by general practitioners in the UK and the Netherlands [1–3].

### Etiology

In moderate climates, the primary pathogen in nonbullous impetigo is *Staphylococcus aureus*. However, in warm and humid climates, *Streptococcus pyogenes* or a combination of *S. pyogenes* and *S. aureus* are often isolated. The relative frequency of *S. aureus* infections has also changed with time. It was predominant in the 1940s and 1950s, and then group-A streptococci became more prevalent. In the last decade of the 20th century, *S. aureus* has been reported to have become more common again [4]. Bullous impetigo is a staphylococcal disease.

### Prognosis

Impetigo is believed to be self-limiting, taking several weeks to cure without intervention. However, no research is available to substantiate this statement. Prompt resolution usually occurs with adequate treatment. The course of the disease is usually mild, but sometimes general symptoms such as fever and lymphadenopathy occur. Streptococcal impetigo can be complicated by nephritis.

### Aims of treatment

Impetigo is treated to accelerate cure and to prevent spreading of the infection.

## Relevant outcomes

Clinical cure (clearance of crusts, blisters, and redness) is the most relevant outcome. Criteria such as relief of pain, itching, and soreness, and bacteriological cure can be considered as secondary outcomes.

## Methods of search

We found four systematic reviews [5–8], the Cochrane review published in 2012 [8] being an extended update of earlier versions [5,7]. As the Cochrane review, with 68 included randomized controlled trials (RCTs), is the most recent and most comprehensive one, it has provided the basis for discussing treatments in this chapter.

The Cochrane review included randomized trials of all interventions for impetigo by using the following search terms in Medline: impetigo (Medical Subject Headings, MeSH) or (MeSH) or impetigo (in title or abstract) or pyoderma (in title or abstract), in combination with the standard search strategy for identifying randomized trials. For this Cochrane review update, the literature was searched up to July 2010. Owing to space limitations, we only report here on nonbullous impetigo, and on the most relevant comparisons and outcomes.

## Questions

### What are the effects of treatments on the clearance of impetiginous lesions after 1 week?

#### Disinfecting treatments

##### Efficacy

**Versus placebo** We found one small randomized trial comparing hexachlorophene with placebo [9]. Scrubbing with hexachlorophene added no notable benefit to placebo treatment.

**Versus topical antibiotic treatment** One multicenter RCT compared hydrogen peroxide cream with fusidic acid cream/gel [10]. There was no significant difference in treatment effect, but there was a tendency towards a better effect of fusidic acid cream/gel. There was

**Figure 40.1** A child with impetigo (reproduced with permission of A.P. Oranje).

no significant difference between hexachlorophene and bacitracin ointment in a small and older study [9].

**Versus oral antibiotic treatment** There was no significant difference between hexachlorophene scrubbing and oral treatment with penicillin [9].

#### **Drawbacks**

Eleven percent of the patients using hydrogen peroxide cream reported mild side effects (not specified). No patient was withdrawn from the study because of side effects [10]. No adverse effects of scrubbing with hexachlorophene were recorded [9].

#### **Comment**

Disinfectants, such as povidone iodine and chlorhexidine advised in some guidelines, have not been compared with a placebo. Hydrogen peroxide cream showed good treatment results in a relatively large trial. However, the procedure for blinding in this trial was considered inappropriate.

#### **Implications for topical disinfectants in clinical practice**

There is no good evidence for the value of disinfecting measures in the treatment of impetigo.

### **Topical antibiotics**

#### **Efficacy**

**Versus placebo** Six studies compared a topical antibiotic with placebo treatment. Mupirocin has been studied in three placebo-controlled trials, all of which found a better effect with mupirocin [11–13]. One other RCT showed that fusidic acid was much more effective than placebo (55% of patients cured vs 13%) [14]. A result of similar magnitude was found for retapamulin versus placebo (86% vs 52%) [15].

**Versus each other** Several topical antibiotics have been compared directly. Mupirocin and fusidic acid were compared in four studies [16–19], none of which showed a significant difference in treatment effect. In a large study (>500 patients), the difference between retapamulin and fusidic acid was not statistically significant [20]. An old study found better results for gentamycin than for neomycin [21].

All other studies comparing topical antibiotics were small and each studied a unique comparison of two antibiotics.

**Versus oral antibiotics** When 10 RCTs that compared topical mupirocin with oral erythromycin were pooled [4,22–30], mupirocin was found to be significantly better than erythromycin [7]. In a small RCT, cephalexin and mupirocin were both significantly more effective than bacitracin cream [31]. A trial in patients with secondarily infected dermatitis found no difference between oral cephalexin and topical retapamulin ointment [32].

#### **Drawbacks**

RCT reports usually note few, if any, side effects with local antibiotics. The two studies comparing mupirocin with placebo reported none [11,12]. In studies comparing mupirocin with fusidic acid, the greasy nature of mupirocin was reported as a side effect in 7% of patients versus 1% [16]; minor itching/burning occurred in 5% versus 4%, respectively [18]. No side effects were reported in Gilbert's study [17]. Studies comparing erythromycin with mupirocin recorded gastrointestinal side effects in 23% versus 8% [4], none in either group [29], and an equal distribution between the two groups [23]. Hydrocortisone/potassium hydroxyquinoline caused two cases (3%) of mild staining [33]. In general, resistance rates against topical antibiotics such as fusidic acid and mupirocin will rise when the antibiotic is used excessively. Retapamulin caused itching in 7% of cases in one study [15] but only 1% in another study [20].

#### **Comments**

Most studies date back 20 years or more. Many RCTs deal with a range of (skin) infections, including impetigo. Only trials that reported separate results for the group of impetigo patients were included here. The follow-up periods and definitions of "cure" and "improvement" differ and are often not clear, making comparison difficult. There is a lack of placebo-controlled studies.

#### **Implications for topical antibiotics in clinical practice**

Although they are traditionally considered less effective than oral therapy, there is good evidence that local treatments are equal to or more effective than oral treatment. In general, oral antibiotics have more side effects, especially gastrointestinal side effects. Fusidic acid, mupirocin, and retapamulin are equally effective. Resistance patterns have changed since then. Contemporary and local characteristics and resistance patterns of the causative bacteria should always be taken into account when choosing treatment. When a large area is affected, or when the patient has general symptoms such as fever, oral therapy seems more appropriate. However, this assumption has never been tested properly.

### **Systemic antibiotics**

#### **Efficacy**

**Versus placebo** Only one small and inconclusive trial was found, comparing systemic antibiotics with placebo [9].

**Versus topical antibiotics** Discussed under topical antibiotics above.

**Versus each other** Two RCTs compared penicillin and erythromycin, both finding erythromycin to be more effective [34,35]. Cloxacillin was significantly superior to penicillin in two studies [36,37]. All other comparisons were each made in only one study,

and none of these showed a relevant difference between treatments.

### Drawbacks

The incidences of side effects were:

- azithromycin – 17%, mainly mild gastrointestinal [38];
- cephalexin – 11%, mainly mild gastrointestinal [38], 11% mainly diarrhea [39], no adverse effects in one study [34];
- cefdinir – 16%, mainly diarrhea [39];
- erythromycin – up to 17% gastrointestinal side effects, mainly diarrhea [40].

### Comments

Many RCTs have been carried out on a range of “soft-tissue” infections, with a subset of impetigo patients. Only trials reporting separate results for the group of impetigo patients were considered in this chapter, although it should be pointed out that most trials in patients with “soft-tissue” infections did not provide results for impetigo separately.

There is a lack of placebo-controlled studies. Resistance rates of the bacteria were determined in some studies, and differed from study to study. The follow-up periods differ widely between the studies, making comparison difficult.

### Implications for use of systemic antibiotics in clinical practice

There is good evidence that local treatment is equal to or more effective than oral treatment. Macrolide antibiotics provide better treatment results than penicillin. In general, oral antibiotics have more side effects than topical treatments, especially gastrointestinal side effects. Most studies date back 20 years or more, and resistance patterns have changed since then. Contemporary local characteristics and the resistance patterns of the causative bacteria should always be taken into account when choosing treatment.

When a large area is affected, or when the patient has general symptoms such as fever, oral therapy seems preferable. As mentioned above, this assumption has never been tested properly.

### Key points

- The natural history of impetigo is not known.
- Few placebo-controlled studies have been done.
- Many different antibiotic treatments have been studied against each other, often in small studies showing no significant differences.
- There is no evidence supporting the value of disinfecting treatments.
- Topical antibiotics such as mupirocin and fusidic acid are equal to or more effective than oral antibiotics such as erythromycin and have fewer side effects.
- Macrolide and cephalosporin antibiotics are more effective than penicillins that are not resistant to beta-lactamase.
- For extensive infections accompanied by general symptoms such as fever, oral antibiotics may be preferable.
- Resistance patterns in causative bacteria change over time, and this should be taken into account when choosing a therapy for impetigo.

<sup>1</sup> Pharmaceutical Sciences Postgraduate Program, Federal University of Paraná, Curitiba, Paraná, Brazil

<sup>2</sup> Pharmacy Department, Federal University of Paraná, Ponta Grossa, Paraná, Brazil

## Background

### Definition

Athlete's foot, or *tinea pedis*, is commonly caused by dermatophyte invasion of the skin of the feet. It is clinically presented as interdigital, moccasin, or vesicobullous forms, with interdigital being the most common. Moccasin infection affects soles, heels, and sides of the feet, characterized by dry and hyperkeratotic skin. With less frequency, vesicobullous is the most severe form of athlete's foot. It appears as an acute and intense inflammation with vesicles, pustules, and bubbles, usually on the soles of feet [1–3] (Figure 41.1).

### Incidence/prevalence

It has been estimated that 15% of the general population have athlete's foot. It is thought to occur when individuals regularly use communal changing rooms and swimming pools. There are studies indicating higher prevalence in male and elderly people [4,5].

### Etiology

Athlete's foot is usually caused by *Trichophyton rubrum*, *Trichophyton mentagrophytes* var. *interdigitale*, and *Epidermophyton floccosum*. Individuals with athlete's foot may be susceptible to secondary bacterial infection with, for instance, group A streptococcus [6].

### Diagnostic tests

Diagnosis of dermatophytosis is based on clinical and laboratory data. Clinical diagnostic procedure must include physical exam of the lesions and epidemiological history survey, whereas mycological tests consist of microorganisms visualization in microscopy and culture growth [2,7,8].

### Aims of treatment

The management of dermatophytosis consists of topical formulations, oral therapy, or a combination of them. An oral drug is needed when the affected area is wide, the patient is immunocompromised, or the disease is chronic or recurrent with failure on topical treatment [2,9].

The aim of treatment is to decrease signs and symptoms, such as redness, itching, and flaking, and also to eradicate the infection,

being that the course of treatment is partially determined by the severity level [1].

Topical antifungals are available as over-the-counter drugs in most countries and are divided into two main classes: azoles, in which the mechanism of action is fungistatic, and allylamines, acting as fungicides. Other “non-azoles” and “non-allylamines,” such as tolnaftate and undecenoic acid, are also commercialized over the counter and, commonly, cost less than the others [2,10].

### Relevant outcomes

The efficacy outcomes evaluated were mycological cure at the end of treatment (MCET) and sustained cure (SC), defined as cure obtained up to 7 days after therapy conclusion and cure maintained for at least 14 days following the end of treatment, respectively. Efficacy of treatment was evaluated by meta-analysis, and the mycological cure was the main outcome considered, evidenced by microscopic negative or absence of growth of dermatophytes in culture [11].

### Methods of search

Systematic reviews and randomized clinical trials (RCTs) were identified using a search strategy published elsewhere [11]. This was updated to June 2012 using the same strategy. We included studies that compared the use of antifungals among themselves or with placebo in the treatment of any clinical form of athlete's foot. Only studies that had patients diagnosed mycologically with the disease were included.

## Questions

### How effective are allylamine creams in the treatment of athlete's foot?

Two meta-analysis published comparing allylamines (terbinafine and naftifine 1%) with placebo, used for 1–4 weeks, show that the two antifungals are similarly effective and better than placebo [5,10].

In a third meta-analysis were identified 12 RCTs ( $n = 1418$ ) comparing naftifine 1% and terbinafine 1% or 3% with placebo,

Figure 41.1 Athlete's foot.

used for 1 day (single-dose) to 28 days. For both efficacy outcomes, allylamines were better than placebo. In terms of MCET, meta-analysis of data from nine RCTs estimated the pooled odds ratio (OR) as 5.87 (95% confidence interval [CI], 2.46–14.01) and number needed to treat (NNT) of 3. For SC outcome, combined data from 11 studies, with follow-up period lasting from 2 to 12 weeks after the cessation of treatment, resulted in an OR of 14.22 (95% CI, 9.49–21.32) and NNT of 2 [12].

### How effective are azole creams in the treatment of athlete's foot?

Two systematic reviews were found comparing the azoles clotrimazole 1%, tioconazole 1%, bifonazole 1%, econazole 1%, and miconazole 2% with placebo, used for 4–6 weeks. The antifungals were similarly effective and better than placebo [5,10].

Another systematic review ( $n = 1223$ ) compared econazole 1%, miconazole 2%, oxiconazole 1%, sertaconazole 2%, and clotrimazole 1% with placebo, used for 28–42 days [12]. For MCET, the data interpolation from seven RCTs resulted in an OR of 5.54 (95% CI, 3.01–10.19) and NNT of 3. For SC outcome, pooled data of four trials with follow-up period lasted from 2 to 4 weeks after the cessation of treatment shows an OR of 6.64 (95% CI, 4.65–9.48) and NNT of 2 [12].

### How do allylamine creams compare with azole creams in curing athlete's foot?

A meta-analysis of nine RCTs ( $n = 1003$ ) indicate better mycological cure rate with allylamines cream (terbinafine and naftifine 1%) in comparison with azoles cream (clotrimazole 1–2% and bifonazole 1%), used for 4–6 weeks. The relative reduction in treatment failure was 37%, favoring allylamines (relative risk [RR], 0.63; 95% CI, 0.42–0.94) [5].

Considering different treatment regimens, data collected at 6 weeks from five trials ( $n = 962$ ), which compared terbinafine 1%

used for 1 week with clotrimazole or miconazole 1% used for 4 weeks, did not show a statistically significant difference in treatment failure (RR, 0.75; 95% CI, 0.33–1.72). However, there was considerable variation in the results of the individual trials [5].

In the study of Patel *et al.* [13], terbinafine was more effective than clotrimazole after 1 week of therapy (RR, 1.51; 95% CI, 1.16–1.98), but there were no differences between the classes in the following weeks.

We performed a meta-analysis of two studies ( $n = 955$ ) [14,15], which compared terbinafine 1% cream twice daily for 1 week and clotrimazole 1% cream twice daily for 4 weeks. Terbinafine was better than clotrimazole for the MCET outcome (OR, 0.28; 95% CI, 0.09–0.85), without differences for the SC outcome, 6 weeks after the end of the treatment (OR, 0.40; 95% CI, 0.07–2.38). A result favoring the use of allylamines (RR, 0.88; 95% CI, 0.78–0.99) was also obtained by Hart *et al.* [10], although some language bias was detected.

In another systematic review, eight trials ( $n = 1300$ ) comparing oxiconazole 1%, clotrimazole 1%, miconazole 2%, or bifonazole 1% with naftifine and terbinafine, both 1%, were pooled. The OR of 0.55 obtained for MCET was statistically favorable to allylamines (95% CI, 0.33–0.92) with an NNT of 41. The results of nine RCTs ( $n = 1523$ ) were interpolated for the SC outcome, giving an OR of 0.39 (95% CI, 0.22–0.67) and NNT of 13, in favor of the allylamines [12].

### How effectively do creams that can be bought in the supermarket cure athlete's foot?

Meta-analysis data indicates that tolnaftate (RR, 1.56; 95% CI, 1.05–2.31) and undecenoic acid (RR, 2.83; 95% CI, 1.91–4.19) are more effective than placebo [5]. We performed a meta-analysis of RCTs comparing ciclopiroxolamine (0.77% and 1%) used for 4 weeks with placebo (three trials,  $n = 654$ ) [16–18]. The ORs obtained were statistically favorable to the antifungal: 6.67 (95% CI, 3.47–12.80) for MCET and 8.98 (95% CI, 2.27–35.53) for the SC outcome. Other studies have similar results [5,10].

Finally, we performed a meta-analysis of four trials ( $n = 711$ ) [19–22] comparing butenafine 1% cream with placebo, used for 1–4 weeks. A result favoring the use of butenafine was obtained for MCET (OR, 7.25; 95% CI, 2.25–23.38) and SC (OR, 12.33; 95% CI, 6.16–24.71) outcomes.

### Are oral drugs more effective than topical formulations in the treatment of athlete's foot?

The major advantage of oral drugs is a decrease on the duration of the treatment, which can improve a patient's compliance [4]. On the other hand, its cost is higher than the treatments based on topical agents, including the costs with medical care.

One RCT ( $n = 137$ ) compared the efficacy of interdigital tinea pedis treatment with oral (terbinafine 250 mg once daily for 1 week) and topical antifungal (clotrimazole 1% cream twice daily for 4 weeks). At week 4, the mycological cure rates were similar for the two drugs (72% for allylamine and 71% for clotrimazole). Although at week 1 the patients treated with terbinafine showed more rapid clinical improvement, higher levels of relapse were observed between weeks 4 and 12 after treatment with this drug (17% vs 5%). Both treatments were well tolerated, with incidence of adverse events equal between the groups [23].

Considering the absence of more studies, it is cautious to reserve treatment with oral antifungals only for several or relapsing cases of athlete's foot, when there is no topical treatment response [24].

## What are the most effective oral drugs in the treatment of athlete's foot?

The efficacy of oral drugs is not influenced by the type of tinea pedis [4].

A meta-analysis of 12 RCTs ( $n = 700$ ) showed no significant differences between terbinafine (250 mg/day for 2 weeks) and itraconazole (100 mg/day for 4 weeks); between fluconazole 50 mg and either itraconazole 100 mg or ketoconazole 200 mg, used for 6 weeks; or between griseofulvin 1000 mg and ketoconazole 200 mg, used for 4 weeks [4].

For the same treatment length (2 weeks), terbinafine 250 mg was more effective than itraconazole 100 mg. Moreover, terbinafine 250 mg cures 52% more patients than griseofulvin 500 mg, when used once daily for 4–6 weeks [4].

Adverse effects were reported for all drugs, with gastrointestinal effects, such as diarrhea and nausea, being the most commonly reported. There were no long-duration or harming adverse events [4]. The oral therapy with terbinafine, itraconazole, and fluconazole was associated with low incidence of adverse events in an immunocompetent population [25].

## What are the most effective topical drugs in the treatment of athlete's foot?

We applied a random-effects Bayesian mixed treatment comparisons (MTC) model to combine placebo-controlled and direct topical antifungals comparison trials. Our analysis included 41 clinical trials published until June 2012 retrieved through a systematic review of the same databases used for conventional meta-analysis [11].

Our analysis did not show statistically significant differences among all pairwise antifungals assessed (bifonazole, butenafine, clotrimazole, ciclopiroxolamine, econazole, flutrimazole, ketoconazole, miconazole, naftifine, oxiconazole, sertaconazole, and terbinafine) for the MCET outcome.

For the SC outcome, the ORs for butenafine, naftifine, and terbinafine were statistically superior to oxiconazole: 5.10 (95% CI, 1.16–22.47), 4.61 (95% CI, 1.23–17.33), and 6.05 (95% CI, 1.74–21.05), respectively. Terbinafine also showed better response when compared with clotrimazole (OR, 2.88; 95% CI, 1.27–6.53). Terbinafine, butenafine, and naftifine, which occupied the first three places in the ranking, might be the best strategies for cure maintenance.

## Drawbacks

Our analysis of published clinical trials has showed no differences in safety in all direct comparisons made between antifungals and placebo and among antifungal class. Few serious adverse events were reported, and the most common adverse events reported were burning, stinging, and itching, all confined to the site of application [11,12].

All oral antifungals were associated with the occurrence of adverse events. The lowest prevalence of events was obtained with fluconazole (11%) and the highest with terbinafine (18%) [4].

## Comments

There is consistent evidence regarding the superiority of antifungals in comparison with placebo. For athlete's foot, allylamines are better than azoles in providing and maintaining mycological cure.

Oral antifungals are not more effective than topical ones in the management of athlete's foot. Additionally, higher rates of infection relapse, adverse events, and costs of the treatment were observed in patients treated with oral agents [7].

## Implications for clinical practice

All topical antifungals (azoles, allylamines, butenafine, ciclopiroxolamine, tolnaftate, and undecenoic acid) can be recommended to the treatment of athlete's foot.

Allylamines are superior to azoles in obtaining and maintaining cure, with the advantage of requiring a shorter period of time that can be associated with greater rates of compliance. Nevertheless, owing to their higher cost compared with other antifungals, an individual analysis for each patient must be done.

Oral therapy must be considered only for severe infections or in relapses cases.

## Key points

- All topical antifungals are better than placebo in the treatment of athlete's foot.
- Direct comparisons of allylamines versus azoles used in the treatment of athlete's foot show allylamines to be generally more efficacious than azoles.
- MTC results do not show statistical differences among the antifungals considering the MCET outcome. Terbinafine, butenafine, and naftifine might be the best strategies for cure maintenance.
- There is evidence to suggest that oral drugs are no more effective than creams in producing a cure for athlete's foot and still produce more adverse events.
- No differences were found in safety in all direct comparisons established between antifungals and placebo and between antifungals with each other.

# Pityriasis versicolor

Nancy Habib and Michael Bigby

Department of Dermatology, Harvard Medical School and Beth Israel Deaconess Medical Center, Boston, MA, USA

## Background

### Definition

Pityriasis versicolor (also known as tinea versicolor) is an infection of the skin caused by the lipophilic yeast genus *Malassezia*, which contains at least 14 species with the modern molecular-genetically based taxonomy; in most cases it is thought to be due to *Malassezia globosa*, although other species such as *Malassezia sympodialis* are likely involved in some cases [1]. The disease is manifested by very thin, scaly plaques that can be hyperpigmented, hypopigmented, or erythematous (Figure 42.1). Lesions are generally asymptomatic, but can be associated with pruritus. The rash may be accompanied by hyper- or hypopigmentation that often persists long after the organism is eradicated. The eruption most commonly affects the torso, neck, ears, and the pubis, but can be widespread. The face may be affected, especially in children [2].

### Incidence/prevalence

The incidence of pityriasis versicolor is not well studied. As the organism grows best in warm and wet conditions, it is more common and more extensive in tropical climates. The prevalence was 2.1% (22/1024) among a representative sample of young Italian sailors [3]. The prevalence was 1.8% among textile workers in Adana, Turkey, 15.5% (140/902) in a fishing village in Rio Seco, Venezuela, 16.6% among a random sample of adults in the Central African Republic, and 3.1% among 4267 people in Sao Paulo, Brazil [4–7]. In a total population survey in Karonga district, Malawi, 8% (4915/61 735) were found to have extensive pityriasis versicolor and an additional 9.9% (6085 people) had mild disease [8].

### Etiology

Pityriasis versicolor is caused by the lipophilic yeast genus *Malassezia*, mostly due to *M. globosa*.

### Prognosis

Untreated, the disease may lessen or remit in colder weather but almost invariably reappears in hot weather. Annual recurrences during hot weather are common in treated and untreated patients.

### Diagnosis

The diagnosis can be established by KOH staining of scales obtained from affected scaly plaques. On microscopy, the organism is easily recognized as spores and hyphae that resemble “spaghetti and meatballs” (Figure 42.2). Identification is enhanced by the addition of blue–black ink and a wetting agent to the KOH preparation. Under Wood’s light examination, pityriasis versicolor fluoresces a light yellow or golden color. The organism can also be cultured, but the culture technique is difficult and not readily available.

### Aims of treatment

The aim of treatment is the eradication of the organism, which can be verified by negative KOH preparations, and resolution of the rash. The hyper- or hypopigmentation may persist after the organism has been eradicated. The aim of interventions for prevention is to prevent annual recurrences during hot weather.

### Relevant outcomes

The primary outcomes of treatment are eradication of the organism, verified by KOH preparations, and resolution of the rash. The primary outcome of prevention is to stop recurrences in hot weather.

### Methods of search

We searched the Cochrane Library, LILACS, Medline, and Embase from inception until August 2012.

## Questions

### What are the effects of topical treatments used for the treatment of pityriasis versicolor?

#### Efficacy

We found one systematic review by Hu and Bigby which showed most topical treatments are effective when compared with placebo, but the data are less conclusive when comparing topical treatments with each other with different dosages and durations [9]. Randomized controlled trials of topical treatments for pityriasis

**Figure 42.1** Pityriasis versicolor most commonly affects the torso but can be widespread.

versicolor have increased over the past decade, but many still involve only a small number of patients [9]. Most topical treatments used to treat pityriasis versicolor (including imidazole antifungal creams or shampoos, zinc pyrithione shampoo, selenium sulfide shampoo, and sulfur–salicylic acid shampoo) are effective when compared with placebo with numbers to treat (NNTs) of 1–2. Topical terbinafine is less effective than other available topical treatments. The largest number of randomized studies on topical imidazoles has involved ketoconazole, followed by clotrimazole and bifonazole.

Of the non-imidazole topical agents, zinc pyrithione, sulfur–salicylic acid, and selenium sulfide have shown the greatest response differences in comparison with placebo. Some studies have assessed the use of other non-imidazole topical agents such as lactic acid, adapalene, 1% diclofenac gel, and *Artemisia sieberi* lotion [10–14]. One small study showed 10% lactic acid solution to have similar effects as clotrimazole 1% solution at the end of 4 weeks, but at the end of 2 weeks more patients in the lactic acid group showed resolution, with a risk difference (RD) of 56 (95% confidence interval [CI], 33–79) and an NNT of 2 [13]. Two studies compared *Artemisia sieberi* lotion with clotrimazole lotion, and after 4 weeks of treatment both studies showed *Artemisia sieberi* to have superior effects to clotrimazole with RDs of 21 (95% CI, 3–39) and 19 (95% CI, 4–33); the NNTs were 5 and 6, respectively [10,11]. In the one study comparing 1% diclofenac gel with clotrimazole cream and placebo cream, 1% diclofenac gel was inferior to treatment with clotrimazole (RD, –36; 95% CI, –58 to –14) but better than placebo (RD, 56; 95% CI, 37–75) [14]. One study compared adapalene with ketoconazole cream, and the results did not reach statistical significance (RD, 8; 95% CI, –12 to +27) [12].

Most trials comparing different active agents or different treatment regimens are underpowered to detect clinically meaningful differences [9]. However, the data suggest that longer durations of

**Figure 42.2** The diagnosis can be established by 10% KOH–50% Parker ink staining of scales obtained from affected scaly macules. On microscopy, the organism is easily recognized as spores and hyphae that resemble “spaghetti and meatballs.”

treatment and higher concentrations of active agents produce greater cure rates. In individual studies, the differences often do not reach statistical significance.

Although optimal regimens have not been established, the data suggest that 1–4 weeks of treatment can be recommended. Ketoconazole shampoo is applied to affected areas, left on for 5–10 min and then washed off. Treatment is repeated daily for 1–4 weeks. The imidazole creams are applied once or twice daily for 1–4 weeks. Creams are more costly than shampoos and no more effective, and therefore are less cost-effective. Selenium sulfide or zinc pyrithione shampoo is applied to affected areas for 5–10 min and then showered off. Treatment is repeated daily for 1–4 weeks. Many of the studies lack follow-up past 1 month after completing treatment, so it is difficult to assess the duration of cures.

### Drawbacks

Topical treatments for pityriasis versicolor are generally well tolerated. They may cause skin irritation or contact allergy. Selenium sulfide is more likely to cause skin dryness and irritation than other available treatments and has a strong odor.

### Comment

The topical treatment of pityriasis versicolor is an area in which evidence and experience coincide.

### Implications for clinical practice

Most topical treatments used to treat pityriasis versicolor (including imidazole antifungal creams or shampoos, zinc pyrithione shampoo, selenium sulfide shampoo, and sulfur–salicylic acid shampoo) are effective when compared with placebo with NNTs of 1–2. Data suggest that longer durations of treatment and higher concentrations of active agents produce greater cure rates. Terbinafine is less effective than other available topical treatments. Selenium sulfide is more likely to cause skin dryness and irritation than other available treatments.

## What are the effects of systemic treatments used for pityriasis versicolor?

### Efficacy

We found one systematic review [9]. Randomized controlled trials of systemic treatments for pityriasis versicolor are generally of low to moderate quality, usually involving small numbers of patients and many lacking blinding or intention to treat analysis [9]. Most systemic treatments used to treat pityriasis versicolor (including oral triazoles and imidazoles) are effective when compared with placebo with NNTs of 1–2. The data are lacking for the efficacy of oral terbinafine in pityriasis versicolor.

Trials comparing different active agents or different treatment regimens are underpowered to detect clinically meaningful differences [9]. However, the data suggest that longer durations of treatment and higher doses produce greater cure rates. In individual studies, the differences often do not reach statistical significance.

Although optimal regimens have not been established, the data suggest that ketoconazole 200 or 400 mg daily for 7–10 days, itraconazole 200 mg daily for 5–7 days, or fluconazole 300 mg weekly for 2–4 weeks can be recommended. One study has also shown pramiconazole 200 mg for 2–3 days to be better than placebo with an RD of 69 (95% CI, 49–89) and an NNT of 2 [15]. Response rates tended to be dose dependent, with single-dose regimens (e.g., ketoconazole 400 mg or fluconazole 450 mg or intraconazole 400 mg) being less effective. However, the NNTs are large and the confidence intervals wide in individual studies.

### Drawbacks

All of the imidazoles and triazoles inhibit the enzyme cytochrome P450 system. Therefore, these agents have many drug–drug interactions. Concomitant administration with other drugs which are metabolized by the cytochrome P450 system should be monitored closely. These agents should not be administered in patients on cisapride, astemizole, and terfenadine owing to potential rare cardiovascular adverse events such as arrhythmias, torsade de pointes, and death.

Ketoconazole carries a **Black Boxed Warning** issued by the US Food and Drug Administration (FDA) because it has been associated with hepatotoxicity, including some fatalities. The frequency is low (134 cases per 100 000 person-months (95% CI, 37–488) in one study), but it is the highest among the oral imidazole antifungals [16]. Liver function tests should be checked if the duration of treatment exceeds 1 week. Ketoconazole administration is contraindicated with use of cisapride for the reasons stated above. High doses of ketoconazole may suppress adrenocortical function. In clinical trials, nausea/vomiting (3–10%), pruritus (2%), and abdominal pain (1%) were reported. Diarrhea, dizziness, fever, gynecomastia (androgen receptor antagonist), and headache occur less frequently.

Itraconazole, a triazole, carries a **Black Boxed Warning** from the FDA for association with development of congestive heart failure (CHF), especially in patients with a history of CHF. Coadministration with cisapride, pimozide, midazolam, triazolam, simvastatin, lovastatin, quinidine, dofetilide, and levomethadyl is contraindicated due to itraconazole's inhibition of the cytochrome P450 system. Rare cases of serious cardiovascular adverse events (including death, QT prolongation, ventricular tachycardia, and torsade de pointes) have been observed when itraconazole is administered with those stated agents. Itraconazole has been associated with rare cases of serious hepatotoxicity (including fatal cases and cases within the first week of treatment). It is, therefore, not recom-

mended for use in patients with active liver disease, elevated liver enzymes, or prior hepatotoxic reactions to other drugs (www.uptodate.com).

In clinical trials with itraconazole, nausea (11%), edema (4%), hypertension (3%), headache (4%), fatigue (2–3%), malaise (1%), fever (3%), rash (9%), pruritus (3%), decreased libido (1%), hypertriglyceridemia, hypokalemia (2%), abdominal pain (2%), anorexia (1%), vomiting (5%), diarrhea (3%), abnormal liver function tests (3%), albuminuria (1%), and dizziness (2%) were reported (www.uptodate.com).

In clinical trials with fluconazole, headache (2–13%), rash (2%), nausea (4–7%), vomiting (2%), abdominal pain (2–6%), and diarrhea (2–3%) were reported. Hepatitis and liver function test elevations are rare and less common than with other azoles. Serious adverse reactions are rare (www.uptodate.com).

### Comment

Treatment with oral azoles is an area in which evidence and experience coincide.

### Implications for clinical practice

Extensive pityriasis versicolor can be successively and safely treated with the oral imidazole antifungals. Because of their effect on the cytochrome P450 system and the associated implications on concentrations of coadministered medications, close evaluation of a patient's medication list is recommended. Data suggest that ketoconazole 200 or 400 mg daily for 7–10 days, itraconazole 200 mg daily for 5–7 days, or fluconazole 300 mg weekly for 2–4 weeks can be recommended.

## What are the effects of topical and systemic regimens used to prevent recurrences of pityriasis versicolor?

### Efficacy

We found one systematic review [9]. There is limited evidence from clinical trials. Itraconazole 200 mg twice daily once per month for 6 months was effective in preventing recurrences compared to placebo (response difference 32%; 95% CI, 20–43%; NNT, 4; 95% CI, 3–5). We found no randomized controlled trials using ketoconazole or fluconazole to prevent recurrences. Case series suggest that ketoconazole weekly or fluconazole monthly may be effective.

We found one randomized controlled clinical trial of topical regimens to prevent recurrences [17]. Two different dosing schedules of topical bifonazole were studied. Conclusions could not be drawn from this study [17].

### Drawbacks

See above.

### Comment

Weekly or monthly doses of azole antifungals are commonly used to prevent recurrences of pityriasis versicolor. Randomized controlled data to support their use are scant for itraconazole and were not found for ketoconazole and fluconazole.

### Implications for clinical practice

A small randomized clinical trial suggests that itraconazole 200 mg twice daily once a month is effective in preventing recurrences. Optimal regimens for ketoconazole and fluconazole have not been established. Optimal regimens for topical prevention have not been established.

## Key points

- The diagnosis of pityriasis versicolor can be easily established by KOH staining of scrapings from affected skin.
- Most topical treatments used to treat pityriasis versicolor (including imidazole antifungal cream or shampoos, zinc pyrithione shampoo, selenium sulfide shampoo, and sulfur/salicylic acid shampoo) are effective when compared with placebo with NNTs of 1–2.
- Post-inflammatory hypopigmentation may persist for several months after successful treatment.
- Extensive pityriasis versicolor can be successively and safely treated with the oral azole antifungals.
- Data suggest that ketoconazole 200 or 400 mg daily for 7–10 days, itraconazole 200 mg daily for 5–7 days, or fluconazole 300 mg weekly for 2–4 weeks can be recommended.
- Optimal regimens for ketoconazole and fluconazole have not been established.
- Caution must be taken with administering oral imidazoles and triazoles with medications which are metabolized by the cytochrome P450 system. Concomitant administration with cisapride, terfenadine, or astemizole is contraindicated.
- Data on prevention of recurrences are sparse. One study has suggested that itraconazole 200 mg twice daily once per month for 6 months was effective in preventing recurrences compared with placebo.
- Optimal regimens for topical prevention have not been established.
- Randomized, controlled clinical trials are needed to establish optimal topical and oral regimens to prevent recurrences.

# Onychomycosis

Aditya K. Gupta,<sup>1,2</sup> Elizabeth A. Cooper,<sup>2</sup> Maryse Paquet,<sup>2</sup> and Fiona Simpson<sup>2</sup>

<sup>1</sup>Department of Medicine, University of Toronto, Toronto, Ontario, Canada

<sup>2</sup>Mediprobe Research Inc., London, Ontario, Canada

## Background

### Definition

Onychomycosis is a fungal infection of the nail caused predominantly by anthropophilic dermatophytes, less commonly by yeast (*Candida* spp.), and by non-dermatophyte mold infections [1–3]. Onychomycosis may present with hyperkeratosis, subungual debris, thickening, or discoloration of the nail plate (Figure 43.1). Total nail dystrophy may also result with advanced onychomycosis [3].

### Incidence/prevalence

Onychomycosis is the most common nail disorder in adults. It accounts for approximately 50% of all nail diseases [4,5] and has increased in individuals over the last 80 years [3]. In North American centers, the prevalence of onychomycosis is between approximately 6.5 and 13.8% [4,6–8]. Onychomycosis predominantly affects toenails in comparison with fingernails; in some reports, the ratio of toenail:fingernail onychomycosis ranges from 4:1 to 19:1 [4,7,9,10].

### Etiology/risk factors

Predisposing factors for onychomycosis include tinea pedis, positive family history, increasing age, male gender, trauma, immunosuppression, diabetes mellitus, poor peripheral circulation, and smoking [3,4,6,7,11–18]. In addition, for fingernails, persistent exposure to water, the use of artificial nails, and trauma induced by pushing back the cuticles and aggressive manicuring may also be predisposing factors.

### Prognosis

Onychomycosis can be effectively treated with systemic and/or topical antifungal agents, as well as device-based therapies. Traditional systemic agents used to treat onychomycosis include griseofulvin. The newer oral agents used to treat onychomycosis are terbinafine, itraconazole, and fluconazole [19–26]. Recent available data suggest that the triazoles ravuconazole and posaconazole are effective for this indication [27,28]. Topical treatments include ciclopirox and amorolfine nail lacquers [29,30]. Only ciclopirox nail lacquer 8% has been approved in the USA for the treatment of onychomycosis [31].

Relapse of onychomycosis, especially in the toenails, is not uncommon, particularly in predisposed individuals. The reasons

why fingernail onychomycosis responds better than toenail disease may be related to the fact that perfusion of the upper extremity is generally better than that of the lower extremity; this may result in improved drug delivery to the fingers in comparison with the toes. Also, fingernails have a faster rate of outgrowth in comparison with toenails (3 mm/month compared with 1 mm/month) [32], resulting in the infected fingernail growing out faster than its lower extremity counterpart.

### Aims of treatment

Onychomycosis may be a cosmetic problem, especially when fingernails are infected [33]. The treatment objectives are to reduce the fungal burden within the nail, ultimately curing the fungal infection, and to promote healthy regrowth of affected nails. In some instances, when onychomycosis is associated with a degree of morbidity – for example, pain, discomfort, or soft-tissue infection – timely treatment may help eliminate symptoms and prevent complications that could be associated with more severe consequences [34].

### Relevant outcomes

The most commonly reported therapeutic measure of efficacy is mycological cure, which is defined by most as a negative light-microscopic examination and negative culture. There are several methods by which clinical improvement has been assessed. Some studies have used the parameter of clinical success, which is defined as “cleared” or “markedly improved” (90–100% clear nail) [35]. Others have defined clinical success as cure or improvement sufficient to reduce the involved area of the target nail to less than 25% at the end of therapy [36]. Another term that has been used is “clinical effectiveness,” which is taken to be mycological cure and at least 5 mm of new clear toenail growth [37]. Clinical cure refers to the post-therapy nail appearing completely cured to the naked eye. The complete cure rate is the combined result of mycological and clinical cure.

These outcomes are typically reported in clinical trials in which one toenail is chosen as the target, and “cure” is based on the target toenail alone. While such standards are necessary to provide points of comparison for clinical efficacy, all affected nails would be cured if a regimen was “successful.” There is a paucity of clinical data including outcomes for all affected toenails during oral therapy, and there is evidence to suggest that not all toenails can be expected

**Figure 43.1** Infection of the nail of the left great toe in a 47-year-old nondiabetic male who had no other health problems. He gave a history of a nail abnormality that had persisted for approximately 15 years, possibly related to previous nail trauma. The thickened nail had large areas of yellowish-white discoloration, typical of fungal nail infection. Culture revealed infection with the dermatophyte fungus *Trichophyton rubrum*.

to have equivalent degrees of clinical cure [38,39]. Clinicians should keep in mind that the outcomes measured in clinical studies may not adequately represent all patients being treated for onychomycosis.

The limitations of standard microscopy and culture methods have been recognized for years, particularly in relation to the high rate of false-negative cultures, but until recently no other reliable methods of fungus identification have been available. Reports on the use of molecular biological methods to identify fungal DNA are increasing [40–44]. These molecular methods provide faster identification relative to the standard microscopy/culture methods. It remains to be seen what impact such analysis may have on fungal treatment. Greater use of such analyses can be expected in the future, particularly if it can be conclusively demonstrated that such methods can provide an analysis of viable fungus present in nails with higher reliability than standard microscopy/culture methods.

## Methods

PubMed, the Cochrane Library, and Embase databases were searched in June 2012 for English-language publications for the best evidence for the different clinical questions presented in this chapter based on the hierarchy principle: first, systematic reviews; second, randomized clinical trials; and third, nonrandomized evidence. Evidence was graded using the quality-of-evidence scale system presented in Chapter 7, and the quality of randomized clinical trials was judged on a clear description of the randomization and concealment of allocation methods, blinding, the type of analysis (i.e., intention-to-treat or per protocol), and the sample sizes.

Onychomycosis caused by *Candida* spp. and nondermatophyte molds is less common and will not be considered in this chapter. The efficacy data presented for the different antifungals would be for the treatment of onychomycosis caused by dermatophytes.

The use of the nail lacquers ciclopirox and amorolfine are discussed, as these agents are approved for use in onychomycosis. There are many anecdotal reports of various other topical agents being effective for the management of onychomycosis; however,

published reports of the efficacy of topical agents in onychomycosis in the indexed, peer-reviewed literature are far fewer. Other clinical trials have included tioconazole 28% solution, bifonazole with urea, fungoid tincture, miconazole, and tea-tree oil. The authors would like to bring to your attention that, subsequent to the literature search for this review, clinical trials results have been published for a new topical solution for the treatment of onychomycosis, efinaconazole 10%. Consequently, the evidence for this new topical treatment is not presented.

The use of other topical agents and cosmetic procedures such as debridement, combined with oral therapy, is not considered here, as most of these studies are single studies and not widely practiced at this time [45–47]. However, support for adjunctive therapy, particularly in the more severe cases of onychomycosis, has increased, in an effort to improve cure rates without increasing exposure to oral medications [48]. Further studies of such combinations are anticipated.

We have not considered trials that used nonstandard regimens such as sequential or combination therapy (with the exception of combination of amorolfine and ciclopirox with oral therapies) and the trials using ketoconazole to treat onychomycosis, given the potential of this agent to cause hepatotoxicity and the availability of alternative agents.

## Questions

### What is the role of oral antifungal therapy in the management of dermatophyte onychomycosis in adults?

Griseofulvin was the first significant oral antifungal agent available for the management of dermatomycoses. Over the years, the use of griseofulvin in the treatment of onychomycosis has decreased, although it is still widely used for the treatment of tinea capitis [49]. Ketoconazole, an oral imidazole, is no longer recommended for the treatment of onychomycosis, which requires a long duration of therapy, due to the potential for hepatotoxicity [49]. The introduction of the new oral antifungal agents terbinafine, itraconazole, and fluconazole has led to improved efficacy rates, decreased treatment duration, and fewer adverse events.

The use of ravuconazole for the management of onychomycosis has not been considered further in this chapter, as only one published report of efficacy is known to us [27]. The treatment of onychomycosis with posaconazole is still under investigation [28].

### What are the effects of systemic treatments on fingernail and on toenail onychomycosis caused by dermatophytes in healthy adults?

#### Griseofulvin

The regimen for treating onychomycosis is continuous therapy using a dosage of 500 mg/day to 1 g/day, typically administered for 6–12 months in fingernail onychomycosis and for 9–18 months in toenail disease.

#### Fingernails (quality of evidence: 2)

One randomized double-blind study compared griseofulvin with terbinafine in the treatment of onychomycosis (Table 43.1) [50]. The methods used for generation of the randomization sequence and for the allocation concealment were not specified and a per-protocol analysis was performed with 20/92 (22%) of participants excluded.

**Table 43.1** Systemic treatments of dermatophyte fingernail onychomycosis.

Year	First author, ref.	Treat.	Study type	Sample size (n)	Regimen	Treat. duration	Follow-up period (from baseline)	Efficacy measure

CC, complete cure; CR, clinical response; DB, double-blind; FLUC, fluconazole; GRIS, griseofulvin; ITRC, itraconazole continuous; ITRP, itraconazole pulse; MC, mycological cure; mo, months; R, randomized; TER, terbinafine; TERC, terbinafine continuous; TERP, terbinafine pulse; Treat., treatment; wk, weeks.

<sup>a</sup>Mycological cure defined as negative microscopy and culture, unless indicated otherwise.

<sup>b</sup>Clinical response defined as cured or markedly improved, unless indicated otherwise.

<sup>c</sup>Complete cure defined as mycological and clinical cure or markedly improved, unless indicated otherwise.

### Fingernails: effectiveness

In a double-blind randomized controlled trial (RCT), griseofulvin was given at a dosage of 500 mg/day for 12 weeks. The mycological cure rate and complete cure rate were 63% and 39%, respectively [50].

### Toenails (quality of evidence: 2)

Three systematic reviews were identified. One systematic review (search date November 2002: three RCTs, 167 participants) used a meta-analysis method to calculate sample-size-weighted cure rates [51]. The three RCTs were double-blind with homogeneous dosing regimens and outcomes. The quality of the RCTs included was not assessed. The second systematic review (search date March 2000: eight RCTs, 319 participants) was associated with high variability in dosing regimen and efficacy outcomes and the results were not

pooled together [52]. No information was given about the blinding of the studies included, though the quality of the studies was assessed but not presented separately for the studies investigating griseofulvin. The last systematic review (search date 1999: four RCTs, one comparative study, 211 participants) also used a meta-analysis method to calculate sample-size-weighted cure rates [53]. Four studies were double blind and one was open. The dosing regimen varies from 500 to 1000 mg daily for 6–12 months. None of these systematic reviews specified the type of analysis (intention-to-treat or per protocol) used by the included studies.

### Toenails: effectiveness

In the RCTs included in the first meta-analysis, 500 or 1000 mg/day of griseofulvin was administered for 1 year to treat onychomycosis. The pooled mycological cure rate was 60 ± 6% [51]. The dosing

regimens used in the studies included in the second systematic review varied from 200 to 1000 mg/day for 6–18 months and the resulting mycological cure rates ranged from 0 to 69% [52]. In the last systematic review including 500 or 1000 mg/day for 6–12 months, the pooled mycological cure rate was  $41.1 \pm 20.4\%$  (standard error, SE) [53].

### Drawbacks

The use of griseofulvin may be associated with adverse events such as gastrointestinal upset, nausea, diarrhea, headache, central nervous system symptoms, and urticaria [49]. No drugs are contraindicated with griseofulvin, and few drug interactions are associated with griseofulvin therapy [49].

### Comments

Griseofulvin was the first systemic agent used to treat onychomycosis on a widespread basis. Currently, the newer oral agents (itraconazole, terbinafine, and fluconazole) have been found to be more effective than griseofulvin; the duration of active therapy is also shorter with the more recently introduced antimycotics [61,62]. Moreover, when griseofulvin is used to treat dermatophyte toenail onychomycosis, relapse rates may be higher (40–60%) [63] in comparison with the newer oral antifungal agents [35,57,64–66].

### Continuous terbinafine

The regimen for fingernail and toenail onychomycosis is 250 mg/day, administered for 6 weeks and 12 weeks, respectively.

#### Fingernails (quality of evidence: 2)

Five RCTs (four double-blind [50,54,56,57], one open [55]) evaluated patients with fingernail onychomycosis. Little information was available on the study presented in terbinafine's label information [57]. One study used a randomized block of four participants [56] and the other three studies did not specify their methods of randomization and allocation concealment. The sample sizes varied from five to 88 participants (Table 43.1). One study [55] reported the efficacy outcome for all randomized participants, whereas the other three studies reported data from per-protocol analysis and one of these studies [50] excluded 24% (21/88) of participants.

#### Fingernails: effectiveness

The studies used terbinafine 250 mg/day for 6 weeks [56,57], 8 weeks [55], and/or 12 weeks [5,50,56] (Table 43.1). Mycological cure was achieved in 79% of patients treated for 6 weeks, 100% for 8 weeks, and 71–92% of patients treated for 12 weeks, whereas complete cure was achieved in 59–75% (6 weeks) and 71–76% (12 weeks).

#### Toenails (quality of evidence: 2)

The efficacy of continuous terbinafine in the treatment of dermatophyte toenail onychomycosis was investigated by five meta-analyses. Two meta-analyses – search date November 2002: 18 RCTs, 993 participants; search date 1999: 19 RCTs, one open, 1393 (mycological), and 1371 (clinical) participants – presented sample-size-weighted cure rates. One review did not specify the individual characteristics of the included studies [51]. The other study included 15 double-blind studies and five open studies [53]. The other three meta-analyses included studies comparing directly continuous terbinafine with pulsed terbinafine (search date January 2011: nine studies (eight RCTs, one retrospective study), 1135 participants) [67], continuous itraconazole (search date March 2000: two RCTs,

501 participants) [52], or pulsed itraconazole (search date March 2008: eight RCTs, 1181 (terbinafine and itraconazole) participants) [68]. The meta-analysis comparing continuous and intermittent terbinafine included three open, two investigator-blinded, and four double-blinded studies (see Pulsed terbinafine, Toenails). The two RCTs included in the comparison between continuous terbinafine and continuous itraconazole were double-blind studies, whereas the comparison between continuous terbinafine and intermittent itraconazole included open and investigator-blinded studies. With the exception of one meta-analysis [67], it was not specified if the data from the studies included were from intention-to-treat or per-protocol analysis.

#### Toenails: effectiveness

A pooled mycological cure rate of  $76 \pm 3\%$  and  $77.2 \pm 4.0\%$  (SE) was obtained with terbinafine 250 mg/day for 12–16 weeks [51,53]. Studies using four different pulsed terbinafine regimens compared with a continuous dosing regimen (250 mg/day for 12–16 weeks) gave a risk ratio (RR) of 0.87 (95% confidence interval [CI], 0.80–0.96;  $P = 0.003$ ;  $n = 8$ ) for per-protocol analysis of mycological cure and 0.93 (95% CI, 0.76–1.13;  $P = 0.44$ ;  $n = 9$ ) for per-protocol analysis of complete cure [67]. Similar results were obtained with intention-to-treat analyses. Thus, the chance of getting a complete cure was similar between the two types of dosing regimens, whereas the pulsed regimen had only 13% less chance than the continuous regimen to result in a mycological cure. In contrast, continuous terbinafine (250 mg/day for 12–16 weeks) was clearly superior to pulsed itraconazole (400 mg/day for 1 week/month, 3–4 months) based on an odds ratio of 2.31 (95% CI, 1.76–3.03;  $P \leq 0.0001$ ;  $n = 8$ ) for mycological cure [68] and to continuous itraconazole (200 mg/day for 12 weeks) based on a risk difference of  $-0.23$  (95% CI,  $-0.15$  to  $-0.32$ ;  $n = 501$ ) for mycological cure [52].

### Drawbacks

The treatment of onychomycosis with terbinafine (continuous) is associated with a low frequency of adverse events [69,70]. These adverse events are generally mild to moderate in severity, and reversible. The most common adverse events involve the gastrointestinal tract, skin, and central nervous system. Only a small proportion of patients discontinue treatment with terbinafine. Pretreatment serum transaminase tests (alanine transaminase and aspartate transaminase) should be considered in all patients before terbinafine therapy is initiated [57]. Terbinafine is an inhibitor of the CYP450 2D6 isozyme, which includes tricyclic antidepressants, selective serotonin reuptake inhibitors, beta-blockers, class 1C antiarrhythmics, and monoamine oxidase inhibitors [57,71,72]. Caution should be used when terbinafine is given to patients using drugs metabolized by CYP 2D6, particularly those drugs with a narrow therapeutic window [57].

### Comments

Terbinafine is effective and safe for the treatment of onychomycosis. Terbinafine is an allylamine that inhibits squalene epoxidase, resulting in an accumulation of squalene and a deficiency of ergosterol. The accumulation of squalene may be associated with fungicidal action [73]. There is a substantial number of high-quality studies that demonstrate the effectiveness of terbinafine (continuous) in the treatment of toenail onychomycosis, and meta-analyses showed its superiority to both continuous and pulsed itraconazole [52,68]. Moreover, a recent meta-analysis comparing the long-term recurrences of toenail onychomycosis showed that continuous ter-

binafine was associated with less mycological recurrences than itraconazole (pulsed and continuous) [74].

### **Pulsed terbinafine**

In contrast to continuous terbinafine, various dosing regimens have been used for intermittent terbinafine therapy.

#### ***Fingernails (quality of evidence: 2)***

Treatment of dermatophyte onychomycosis in fingernails with intermittent regimen of terbinafine has been investigated in three RCTs [55,75,76]. Only one open RCT reported separately the efficacy outcome for toenails and fingernails [55]. The participants were sequentially assigned to one of the three arms of this study and there was no drop out in the participants with fingernail onychomycosis in the intermittent terbinafine arm.

#### ***Fingernails: effectiveness***

Only four out of 21 participants randomized to the pulsed terbinafine had both fingernail and toenail onychomycosis and were treated with terbinafine 500 mg/day for 1 week per month for 4 months. All participants had mycological cure, but 75% (3/4) had complete cure of the fingernails (Table 43.1) [55].

#### ***Toenails (quality of evidence: 2)***

To our knowledge, four different pulse regimens have been investigated in clinical trials for terbinafine. These four regimens were analyzed in a subgroup meta-analysis including studies comparing directly continuous terbinafine with pulsed terbinafine (search date January 2011: nine studies (eight RCTs, one retrospective study), 1182 participants) [67]. Two investigator-blinded studies used two pulses of 250 mg/day for 4 weeks on and 4 weeks off [77,78]. Two double-blind studies used three pulses of 350 mg/day for 2 weeks on and 2 weeks off [79]. One open study and one double-blind study used three pulses of 500 mg/day for 1 week on and 3 weeks off [80,81]. Two open studies and one double-blind study used four pulses of 500 mg/day for 1 week on and 3 weeks off [55,82,83]. Separate analyses were performed for intention-to-treat and per-protocol data.

#### ***Toenails: effectiveness***

When all pulse regimens were pooled together, the efficacy of the pulse regimen was slightly inferior to the continuous terbinafine for mycological cure, but not for complete cure (see Continuous terbinafine/Toenails: effectiveness). Based on per-protocol analysis of RRs for mycological and complete cures, three pulses of terbinafine 350 mg/day for 2 weeks on/2 weeks off or 500 mg/day for 1 week on/3 weeks off were less effective than two pulses of 250 mg/day for 4 weeks on/4 weeks off or four pulses of 500 mg/day for 1 week on /3 weeks off when compared with continuous terbinafine [67].

### **Drawbacks**

Intermittent terbinafine therapy has been associated with few adverse events. Adverse events are generally mild to moderate, and reversible. The spectrum of adverse effects is similar to that seen with the continuous terbinafine regimen [78–82]. A terbinafine (pulse) regimen is not indicated for the treatment of onychomycosis, and therefore there are no monitoring guidelines in the USA.

### **Comments**

The preferred regimen for the treatment of onychomycosis using terbinafine is continuous rather than pulse therapy. Moreover, there

is no evidence so far that an intermittent terbinafine therapy might be more advantageous in terms of cost, compliance, adverse events, or fungal resistance [67].

### **Pulse itraconazole**

Itraconazole pulse therapy is taken to be 200 mg twice a day for 1 week, followed by 3 weeks off between successive pulses. Typically, two pulses are administered for fingernail onychomycosis and three or four pulses for toenail disease. Pulse dosing is the regimen approved by the Food and Drugs Administration (FDA) regimen for infections of the fingernails when no toenail involvement has been noted [66].

#### ***Fingernails (quality of evidence: 2)***

The efficacy of intermittent itraconazole in the treatment of dermatophyte fingernail onychomycosis was investigated in one meta-analysis [58]. This meta-analysis (search date before 1998: 210 (two pulses) and 217 (three pulses) participants) presented sample-size-weighted cure rates without specifying the individual characteristics of the studies included (Table 43.1).

#### ***Fingernails: effectiveness***

Itraconazole was given 400 mg/day for 1 week per month for 2 or 3 months. The mycological cure rates obtained were  $87 \pm 8\%$  (SE) and  $97 \pm 1\%$  and the clinical response rates were  $89 \pm 6\%$  and  $98 \pm 1\%$ , respectively (Table 43.1).

#### ***Toenails (quality of evidence: 2)***

The efficacy of intermittent itraconazole in the treatment of dermatophyte toenail onychomycosis was investigated in four meta-analyses. Two meta-analyses – search date November 2002: six RCTs, 318 (mycological) and 329 (clinical) participants [51]; search date before 1998: 1389 (three pulses) or 259 (four pulses) participants [58] – presented sample-size-weighted cure rates without specifying the individual characteristics of the studies included. The third meta-analysis (search date 1999: six RCTs, five open studies, 1486 (mycological) or 1610 (clinical) participants) also presented sample-size-weighted cure rates and included four double-blind studies and seven open studies [53]. The last meta-analysis included studies comparing directly pulsed itraconazole with continuous terbinafine (search date March 2008: eight RCTs, 1181 (terbinafine and itraconazole) participants) [68]. No systematic review was found for comparison between pulsed and continuous itraconazole, but one double-blind placebo-controlled RCT investigated the efficacy of the two dosing regimens for toenail onychomycosis only [84]. Three of the 65 participants (4.6%) in the continuous itraconazole group and five of the 64 participants (7.8%) in the pulsed itraconazole group discontinued or were excluded from the study. The type of analysis used for the efficacy data was not explicitly stated.

#### ***Toenails: effectiveness***

In the earliest meta-analysis, similar pooled mycological cure rates were obtained for three ( $77 \pm 5\%$  (SE)) and four ( $78 \pm 4\%$ ) pulses, but not for clinical response rates (three pulses:  $82 \pm 3\%$ ; four pulses:  $92 \pm 3\%$ ) [58]. A mycological cure rates of  $63 \pm 7\%$ , and  $70.8 \pm 5.7\%$  (SE) and a clinical response (cure or markedly improved) rates of  $70 \pm 11\%$  and  $73.6 \pm 4.6\%$  (SE) were obtained when pooling the results from studies using itraconazole 400 mg/day 1 week per month for 3–4 months [51,53]. As previously mentioned in the section on terbinafine, intermittent itraconazole

therapy with the same dosing regimen has been shown to be inferior to continuous terbinafine regimen for both mycological and clinical cures [68]. No difference in mycological or clinical cure was observed at 12-month follow-up after 3 months of pulsed itraconazole (400 mg/day, 1 week per month) and 3 months of continuous itraconazole (200 mg/day) [84].

### Drawbacks

Itraconazole (pulse) therapy is approved for fingernail, but not toenail, onychomycosis in the USA [66]. Adverse events occur with a low frequency and are generally mild to moderate in severity, and reversible. These events include gastrointestinal upset, cutaneous eruption, and headache [58]. Studies report a low discontinuation rate due to an adverse event. Itraconazole has the potential for numerous drug interactions, and a thorough review of current medications being used by the patient is required before prescribing [66,71,72,85]. In some cases, the drug interaction may be explained on the basis of an inhibition of cytochrome P450 3A4 by itraconazole. Itraconazole is contraindicated with cisapride, pimozide, quinidine, dofetilide, and levacetylmethadol (levomethadyl) [66,85]. Itraconazole is contraindicated in the USA and Canada in patients with evidence of ventricular dysfunction – for example, congestive heart failure or a history of heart failure [66]. Liver function monitoring should be done in patients with preexisting hepatic function abnormalities or a history of liver toxicity with a previous medication, and should be considered for all patients using itraconazole [66].

### Comments

Itraconazole pulse therapy is effective and safe in onychomycosis. The pulse regimen used to treat toenail onychomycosis decreases the itraconazole required by one-half in comparison with the continuous regimen with this triazole. This may result in cost savings and increased compliance and may reduce the frequency of adverse events [58,86–89]. In fact, the pulse regimen is the preferred mode of drug delivery when using itraconazole. No significant difference was found between three-pulse and four-pulse regimens of itraconazole for the primary efficacy parameters in the treatment of toenail onychomycosis [90]. As previously mentioned, a recent meta-analysis of comparing the long-term recurrences of toenail onychomycosis showed that itraconazole therapy (pulsed and continuous) was associated with more mycological recurrences than continuous terbinafine [74].

### Continuous itraconazole

The regimen for fingernail and toenail onychomycosis is 200 mg/day administered for 6 weeks and 12 weeks, respectively. Continuous itraconazole is used infrequently in current practice, in favor of the pulse itraconazole regimen.

### Fingernails (quality of evidence: 2)

No RCTs have been published on the use of continuous itraconazole for fingernail onychomycosis only. A meta-analysis of early clinical trials with similar protocols (search date before 1998: eight studies (five placebo controlled, three open studies),  $n = 211$  participants) used a modified Der Simonian and Laird method for single group analysis [58]. No further details were given on the individual studies.

### Fingernails: effectiveness

Pooled mycological and clinical response rates of  $86 \pm 3\%$  (SE) and  $90 \pm 2\%$  (SE) were obtained with itraconazole therapy of 200 mg/day for 6 weeks (Table 43.1) [58].

### Toenails (quality of evidence: 2)

Efficacy of continuous itraconazole for toenail onychomycosis was investigated in four meta-analyses. Two meta-analyses – search date November 2002: seven RCTs, 1131 participants [51]; search date before 1998: 20 studies (five placebo controlled, six comparative, nine open), 1741 participants [58] – presented sample-size-weighted cure rates without specifying the individual characteristics of the studies included. The third meta-analysis (search date 1999: 12 RCTs, 1562 participants) also calculated sample-size-weighted cure rates and included 10 double-blind studies, one open study, and one study with no specified blinding [53]. The last meta-analysis included studies comparing directly continuous itraconazole and continuous terbinafine (search date March 2000: two RCTs, 501 (itraconazole and terbinafine) participants) [52]. As previously mentioned for the intermittent itraconazole regimen, no systemic review was found for comparison between pulsed and continuous itraconazole, but one double-blind placebo-controlled RCT investigated the efficacy of the two dosing regimens for toenail onychomycosis only [84].

### Toenails: effectiveness

In the earliest meta-analysis, a pooled mycological cure rate of  $74 \pm 3\%$  (SE) was obtained with 200 mg/day itraconazole for 3 months [58]. A pooled mycological cure rate of  $59 \pm 5\%$  and  $66.3 \pm 4.2\%$  (SE) was obtained for itraconazole 200 mg/day for 3–4 months [51,53]. Itraconazole 200 mg/day for 3 months was found to be as effective as pulsed itraconazole (see Pulse itraconazole/Toenails: effectiveness), but less effective than continuous terbinafine (see Continuous terbinafine/Toenails: effectiveness).

### Drawbacks

Adverse events associated with the use of continuous itraconazole for the treatment of onychomycosis are not common, and those experienced are generally mild to moderate in severity. Adverse events include gastrointestinal disorders (e.g., nausea, abdominal pain), rashes, and central nervous system effects (e.g., headache) [58,84,87–89]. Only a small proportion of patients discontinue treatment with the triazole. There are drugs that are contraindicated with itraconazole (see Pulse itraconazole/Drawbacks). In addition, the triazole has several drug interactions (see Pulse itraconazole/Drawbacks). Itraconazole is contraindicated in North America in patients with evidence of ventricular dysfunction – for example, congestive heart failure or a history of heart failure. The US package insert suggests that liver function tests should be considered for all patients receiving continuous therapy [66]. Treatment should be stopped immediately and liver function tests should be performed whenever a patient develops signs and symptoms suggestive of liver disease [66].

### Comments

Continuous itraconazole therapy is an effective and well-tolerated treatment for onychomycosis. Historically, the treatment of onychomycosis with itraconazole was with the continuous regimen; later, work done by de Doncker *et al.* [89,90] resulted in the widespread adaptation of pulse therapy for this indication. The US package insert states that when patients with toenail onychomycosis were treated with itraconazole continuous therapy, 21% of the overall success group had a relapse (worsening of the global score or conversion of KOH or culture from negative to positive) [66].

### Fluconazole

Various fluconazole weekly dosing regimens have been used for dermatophyte onychomycosis. The dosage varied from 150 mg/

week to 450 mg/week and the duration from 12 to 48 weeks. A recent systematic review showed that the efficacy was not improved by increasing the fluconazole dose but a better efficacy was obtained with treatment longer than 6 months [91]. Consequently, 150 mg of fluconazole weekly for more than 24 weeks is recommended, and the evidence for this dosing regimen (150–450 mg) longer than 6 months will be presented in the following sections.

### **Fingernails (quality of evidence: 2)**

A systematic review (search date January 2012: two studies (one RCT, one nonrandomized),  $n = 243$  participants) presented cure rates for per-protocol analysis [91]. The two studies included are presented in Table 43.1. The RCT was double blind and placebo controlled [60] and the open nonrandomized study included both fingernail and toenail onychomycosis [59].

### **Fingernails: effectiveness**

The mycological cure rates obtained for 150–450 mg fluconazole administered weekly vary from 90 to 99% and the complete cure rates vary from 78 to 91% (Table 43.1).

### **Toenails (quality of evidence: 2)**

Two systematic reviews investigated the efficacy of fluconazole for toenail onychomycosis caused by dermatophytes. The first review (search date 1999: four studies (two RCTs, two open), 288 (mycological) or 292 (clinical) participants) calculated sample-size-weighted cure rates and included two double-blind studies and two open studies [53]. The other systematic review (search date January 2012: four studies (three RCTs, one nonrandomized),  $n = 590$  participants) calculated unweighted mean cure rates obtained for per-protocol analysis [91]. The three RCTs were double blind and placebo controlled, and the open nonrandomized study presented separately data for fingernail and toenail onychomycosis.

### **Toenails: effectiveness**

A mean mycological cure rate of  $61.7 \pm 8.1\%$  (standard deviation, SD) and a mean clinical cure rate of  $46.7 \pm 11.9\%$  were obtained with fluconazole therapy of 150–450 mg weekly for more than 24 weeks [91]. A pooled mycological rate of  $65.6 \pm 7.1\%$  (SE) and a pooled clinical response (cure or markedly improved) rate of  $66.5 \pm 11.7\%$  (SE) were obtained with 150 mg weekly for 3–12 months [53].

### **Drawbacks**

Fluconazole is not approved for the treatment of onychomycosis in North America. The more common adverse effects observed with fluconazole affect the gastrointestinal tract, cutaneous system, and central nervous system [72,92]. Adverse events do not commonly occur, and those experienced are usually of mild to moderate severity and reversible. Only a small proportion of patients discontinue treatment with fluconazole. The drugs contraindicated with fluconazole are cisapride and terfenadine. There are some drug interactions that may occur with the triazole; in certain cases, the drug interactions may be explained by fluconazole inhibiting cytochrome P450 2C9, and at higher doses the triazole may inhibit cytochrome P450 3A4 [71,72].

### **Comments**

Fluconazole is effective and safe in onychomycosis. In comparison with terbinafine and itraconazole, there are relatively few studies that have evaluated the efficacy of fluconazole in the treatment of

toenail onychomycosis. The preferred regimen for fluconazole is once-weekly therapy; typically, 150 mg per week administered for more than 6 months. In the study reported by Scher *et al.*, the clinical relapse rate over a 6-month follow-up was 4.4% [36].

### **Posaconazole**

Four dosing regimens of an oral suspension of posaconazole have been investigated for the treatment of toenail onychomycosis caused by dermatophytes: 100 mg/day for 24 weeks, 200 mg/day for 24 weeks, 400 mg/day for 12 weeks, and 400 mg/day for 24 weeks. Higher efficacy was obtained with 200 mg and 400 mg daily for 24 weeks [28].

### **Fingernails (quality of evidence: no evidence found)**

There was no publication on the efficacy of posaconazole therapy for fingernail onychomycosis.

### **Toenails: (quality of evidence: 2)**

One RCT compared four different regimens of posaconazole with terbinafine (250 mg/day for 12 weeks, investigator blinded) and placebo (double blind) [28]. The participants were randomized according to a computer-generated randomization schedule using a central interactive voice response system. An intention-to-treat analysis (modified and unmodified) was used for the primary efficacy outcome, but the study had small sample sizes.

### **Toenails: effectiveness**

At week 48 assessment, the mycological cure rates were respectively 70% (26/37) and 79% (26/33) for 200 mg and 400 mg for 24 weeks. The corresponding complete cure rates were 54% (20/37) and 46% (15/33). These rates were obtained based on modified intention-to-treat analysis including randomized participants who received at least one dose of posaconazole and with one postbaseline assessment.

### **Drawbacks**

Posaconazole is approved for the prophylaxis of invasive *Aspergillus* and *Candida* infections and the treatment of oropharyngeal candidiasis, but not for onychomycosis [93]. The adverse events observed during treatment of onychomycosis were mild to moderate in severity. The most commonly reported treatment-related adverse events were diarrhea (5%), nausea (4%), dizziness (4%), and headache (6%). A small proportion of patients (4%) discontinue treatment with posaconazole because of adverse events [28]. The drugs contraindicated with posaconazole are sirolimus, CYP3A4 substrates such as pimozide and quinidine, simvastatin, and ergot alkaloids [93].

### **Comments**

The higher concentration of 400 mg did not result in higher efficacy compared with the 200 mg regimen. The regimens of 200 and 400 mg posaconazole daily for 24 weeks had similar mycological cure rates and numerically, but not statistically, higher complete cure rates compared with the terbinafine arm included in the study (250 mg daily for 12 weeks; mycological: 71%; complete: 36%). However, when administered only for 12 weeks, 400 mg/day posaconazole was clearly inferior to terbinafine for the same therapy duration (mycological: 43%; complete: 20%) [28]. Thus, the duration of the posaconazole therapy must be much longer to be as effective as terbinafine. This is consistent with their *in vitro*

antifungal activities for dermatophytes [94]. In contrast, posaconazole had been shown to be more effective than terbinafine in vitro for non-dermatophyte molds and yeasts [94], but the efficacy of posaconazole therapy for the treatment of onychomycosis caused by these agents has not been investigated yet.

### **What are the effects of topical nail lacquers on toenail onychomycosis?**

Nail lacquers provide a direct application of antifungal medication, with the lacquer formulation providing a stable matrix of concentrated medication that aids drug penetration. Topical medications are associated with fewer and less severe adverse events than oral medications, and with less potential for drug interaction than use of oral antifungals. These make topical lacquers a desirable mode of antifungal treatment.

#### **Amorolfine nail lacquer**

Amorolfine 5% nail lacquer can be used once or twice weekly for 6 months for toenail onychomycosis.

#### **Quality of evidence: 2**

One randomized study reporting cure rates investigated amorolfine lacquer therapy for fingernail and/or toenail onychomycosis caused by dermatophytes only. This study was an open study comparing once-weekly versus twice-weekly application of the nail lacquer [95]. Per-protocol results were presented and 42% (169/405) of the participants were not included in the analysis (Table 43.2).

#### **Effectiveness**

Follow-up at 3 months posttreatment (month 9 of the study) showed mycological and complete cure rates of 77% and 47%, respectively (Table 43.2).

#### **Drawbacks**

The patients should have no matrix involvement [102]. No further research has been reported on the use of amorolfine monotherapy.

#### **Comments**

Amorolfine has few safety concerns in comparison with oral therapy, with mild topical irritation being the most prevalent event. One patient who inadvertently used amorolfine twice daily rather than twice weekly reported no irritation [103]. Amorolfine may be an effective treatment for patients with milder, nonmatrix onychomycosis. Amorolfine nail lacquer once every 2 weeks has also been successfully used to prevent onychomycosis recurrence [104].

#### **Amorolfine nail lacquer combined with oral antifungal therapy**

Five trials have used amorolfine in combination with oral antifungals: one using continuous griseofulvin [96], three using continuous terbinafine [75,97,98], and one using continuous itraconazole [99]. All trials involved onychomycosis with matrix involvement.

#### **Amorolfine with griseofulvin (quality of evidence: 2)**

One open randomized study compared combined amorolfine nail lacquer and shorter griseofulvin therapy and longer monotherapy with griseofulvin [96]. Results from per-protocol analysis were presented and 32% (29/91) and 45% (41/91) of the participants were excluded of the analysis for the combined therapy and griseofulvin-only groups (Table 43.2).

#### **Amorolfine with griseofulvin: effectiveness**

Two months of twice-daily griseofulvin combined with twice-weekly amorolfine for 12 months resulted in similar mycological and clinical cures as 12 months of continuous griseofulvin therapy (twice daily for 2 months and once daily for the following 10 months) (Table 43.1).

#### **Amorolfine with terbinafine (quality of evidence: 2)**

Three RCTs investigated the efficacy of 5% amorolfine nail lacquer combined with systemic terbinafine compared with monotherapy with terbinafine for dermatophyte onychomycosis. Two studies were open, included participants with toenail onychomycosis only, and presented results from intention-to-treat analysis [97,98], whereas the other study was also open but included both fingernail and toenail onychomycosis and presented data from per-protocol analysis [75]. This latter study included participants with onychomycosis caused by dermatophytes, non-dermatophyte molds, and yeasts and did not specify the number of participants with confirmed dermatophyte onychomycosis randomized to the three arms of the study by using a table of random numbers.

#### **Amorolfine with terbinafine: effectiveness**

Complete cure rates obtained for continuous terbinafine for 12 weeks combined with 15 months of weekly application of 5% amorolfine nail lacquer (59–72%) were superior to the complete cure rates obtained with the terbinafine monotherapy for 12 weeks (38–45%) for the treatment of toenails (Table 43.2) [97,98]. Weekly amorolfine nail lacquer combined with pulse terbinafine (500 mg daily for 1 week per month) for 4 months resulted in a similar mycological cure rate (86%) to the pulse terbinafine monotherapy (89%) for fingernail/toenail dermatophyte onychomycosis (Table 43.2) [75].

#### **Amorolfine with itraconazole (quality of evidence: 2)**

There was no study reporting efficacy data for onychomycosis caused by dermatophytes only. However, one open RCT with 75% of participants with toenail onychomycosis caused by dermatophytes compared continuous itraconazole therapy with and without amorolfine nail lacquer [99]. Results from per-protocol analysis were presented, but statistical analyses were performed and significant for both per-protocol and intention-to-treat analyses. More participants were excluded from the per-protocol analysis in the itraconazole + placebo group (11/43 = 26%) than the two itraconazole + amorolfine arms (8/51 = 16% and 4/37 = 11%) (Table 43.2).

#### **Amorolfine with itraconazole: effectiveness**

Combined use of amorolfine once weekly for 24 weeks with continuous itraconazole for 12 weeks showed a complete cure rate at week 24 of 94%, versus 69% for continuous itraconazole alone [99].

#### **Drawbacks**

The open design may produce some bias in assessment. Blinded studies should be done to confirm the results. There was a relatively high drop-out rate, with many patients leaving due to lack of efficacy.

#### **Comments**

The rate and type of adverse events noted with combination therapies were similar to those noted with the respective monotherapies. Combination therapy may increase efficacy, but further blinded

<sup>d</sup>Effective cure defined as mycological and >90% reduction in the disease area from baseline.

trials should be carried out to investigate combination therapy with amorolfine.

### Ciclopirox 8% nail lacquer

Ciclopirox 8% nail lacquer is recommended for use once daily for 48 weeks in mild to moderate onychomycosis. This is the first topical therapy to be approved for use in onychomycosis in the USA and Canada.

#### Fingernails (quality of evidence: no evidence found)

Studies investigating ciclopirox nail lacquer treatment for fingernail onychomycosis were not found.

#### Toenails (quality of evidence: 2)

One meta-analysis (search date 1999: 10 studies (two RCTs, eight open), 2027 (mycological) or 2174 (clinical) participants) was identified. This meta-analysis calculated sample-size-weighted cure rates and included two double-blind and eight open studies [53]. The results from one investigator-blinded RCT comparing the traditional 8% ciclopirox formulation with a new formulation (P-3051) are also presented [100]. In this placebo-controlled study, the participants were randomized by using an uneven block of five for the three study arms and a per-protocol analysis was performed (Table 43.2).

#### Toenails: effectiveness

The pooled mycological cure rate was  $52.6 \pm 4.2\%$  (SE) and the clinical response (cure or markedly improved) rate was  $52.4 \pm 9.0\%$  (SE) (Table 43.2) [53]. A better complete cure rate was obtained with the new formulation (13%) compared with the traditional formulation (6%) (Table 43.2) [100].

#### Drawbacks

Further data on the use of ciclopirox for the treatment of dermatophyte onychomycosis in blinded trials are needed.

#### Comments

Adverse events were noted rarely with ciclopirox use [105]. Most reactions were localized to the application site, mild in intensity, and transient. No serious adverse events were reported. Two open-label studies have showed clinical improvement with ciclopirox

therapy for 63–89% of onychomycosis patients with diabetes [106,107].

### Ciclopirox 8% nail lacquer combined with oral antifungal therapy

#### Ciclopirox with terbinafine: (quality of evidence: 2)

Three RCTs comparing monotherapy for terbinafine and combined therapy with ciclopirox nail lacquer for treatment of dermatophyte onychomycosis were identified. Two studies included participants with infected fingernails and/or toenails [75,101], and one study included participants with infected toenails [77]. The blinding and randomization methods were not specified for one study [101]. One study was open and used a table of random numbers for the participants' randomization [75], and the last study was investigator blind and used a predetermined randomization schedule [77]. Per-protocol analysis was generally used with the exception of the mycological cure rates reported in the investigator-blinded study.

#### Ciclopirox with terbinafine: effectiveness

Both continuous [77,101] and pulse [75,77] terbinafine regimens have been combined with ciclopirox nail lacquer. Combination of ciclopirox applied daily for 9 months and terbinafine daily for 4 months resulted in higher mycological cure (88% vs 65%), clinical response (82% vs 59%), and complete cure (68% vs 50%) compared with daily terbinafine for 4 months (Table 43.2) [101]. Longer therapy with daily ciclopirox daily (48 weeks) combined with shorter daily terbinafine therapy (3 months) resulted in higher mycological cure (70% vs 56%), but comparable clinical response (38% vs 44%) or effective cure (33% vs 35%) than 3 months of daily terbinafine only (Table 43.2) [77]. In the same study, a pulse terbinafine regimen (daily for 4 weeks on, 4 weeks off, and 4 weeks on) combined with daily ciclopirox for 48 weeks resulted in similar cure rates to the continuous regimen (Table 43.2). A similar mycological cure rate was also observed with pulse terbinafine (500 mg daily for 1 week per month for 4 months) with (89%) and without (89%) ciclopirox nail lacquer daily for 4 months (Table 43.2) [75].

#### Drawbacks

The number of patients in each study is relatively low. Further blinded trials are needed in order to increase the data available on

the use of ciclopirox in combination with oral antifungals to determine if combination therapy would result in higher efficacy.

### Comments

Most adverse events possibly related to study medication in the blinded trial were minimal and evenly distributed between the treatment groups [77].

## What are the effects of device-based therapies on toenail onychomycosis?

### Laser device systems

Laser device systems use photoselective effects to kill the fungal infection in the nail plate, so that new nail growth can replace the infected portion of the nail plate.

### Toenails (quality of evidence: 2)

One double-blind RCT was found for the treatment of onychomycosis with lasers (Table 43.3) [108,109]. The patients received treatment or sham and the clinical outcome was assessed by both an unblinded investigator and a blinded panel. The efficacy outcomes were presented for treated nails, not for the randomized partici-

pants. Several single-assignment open-label studies have also been conducted on neodymium-yttrium-aluminum garnet (Nd:YAG) and diode laser device systems with various laser models and treatment paradigms (Table 43.3) [110–116].

### Toenails: effectiveness

There was a lot of variability in the definition of the efficacy outcomes presented in the studies (Table 43.3). Cure rates were presented as per patients or per-treated nails. The exact definition of the mycological cure was not always given, but it was generally defined as negative culture. A low mycological cure rate of 50–59% of the nails was obtained in the RCT compared with the other studies, where up to 100% of the patients were cured. A rate for clinical response of 8% of the treated nails was obtained in the RCT. Complete cure rates were higher at 6-month follow-up (39–51% of the treated nails) compared with 9-month follow-up (8%).

### Drawbacks

Laser device systems are new technology and the studies conducted thus far have been limited in terms of sample size and methodology. Owing to the limited duration of the follow-up periods

**Table 43.3** Laser therapies for toenail onychomycosis.

Year	First author, ref.	Treatment	Study type	Patients (n)	Regimen	Treatment duration	Follow-up period (from baseline)	Efficacy measure

<sup>d</sup>Negative culture with at least 3 mm of clear nail growth.

<sup>e</sup>Clinical cure with mycological cure.

<sup>f</sup>Clear nail with negative microscopy.

posttreatment, we are unable to predict the length of the efficacy of laser treatment.

### Comments

Lasers have shown no adverse effects, other than sensation during treatment.

### Photodynamic therapy

Photodynamic therapy (PDT) uses the application of a topical photosensitizing agents and exposure to red or blue light to activate the photosensitizer in order to generate the free radicals to kill the fungi. There are two commercially available photosensitizers that have been tested off-label for use in onychomycosis: 5-aminolevulinic acid and methylaminolevulinate (MAL).

### Toenails (quality of evidence: 2)

No RCTs were found for the treatment of onychomycosis with PDT. One single-assignment open label study investigated MAL-PDT for toenail onychomycosis [117].

### Toenails: effectiveness

After 10 nights of pretreatment with 20% urea ointment, participants applied 16% MAL for 3 h and their nail plates were irradiated with a 570–630 nm light source for a total of three treatments at 2 week intervals [117]. Mycological, clinical, and complete cure rates of 37% at 18 months were found.

### Drawbacks

There is only a single clinical trial and several case studies to support the use of PDT in onychomycosis.

### Iontophoresis

Iontophoresis uses electrical current to increase transungual uptake of terbinafine.

### Toenails (quality of evidence: 2)

A randomized, open, active-comparator study of terbinafine gel with and without iontophoresis was conducted using per-protocol analysis [118].

### Toenails: effectiveness

Participants applied a gel terbinafine patch for 4 weeks and the iontophoresis group received two treatments of 100  $\mu$ A/cm<sup>2</sup> at weeks 2 and 4 [118]. An 84% mycological cure rate (negative microscopy) at 12-week follow-up was obtained.

### Drawbacks

There are no RCTs of iontophoresis with follow-up at time periods greater than 3 months.

## General comments

There have been several pharmacoeconomic analyses of the various oral and topical treatments used in dermatophyte onychomycosis. These studies calculate the cost-effectiveness of each therapy on the basis of the efficacy results of multiple clinical trials. The most cost-effective regimens of oral antifungals for the treatment of onychomycosis are terbinafine (continuous) and itraconazole (pulse) [119,120]. Two studies comparing topical ciclopirox with the two systemic antifungals showed its inferiority to terbinafine and its superiority to itraconazole [121,122]. Combined therapy of the two

antifungals with amorolfine nail lacquer was also superior to the monotherapies [98,123].

In certain nail presentations, the response to therapy may be improved by combining oral antifungal therapy with either an effective topical therapy or mechanical/chemical measures (e.g., mechanical avulsion, debridement, or chemical avulsion). For example, when there is lateral onychomycosis, a dermatophytoma, severe onycholysis, a thickened nail, or severe onychomycosis, it may be advantageous to consider a combination approach [97,124–128].

### Key points

- The main oral antifungal agents used to treat onychomycosis are terbinafine, itraconazole, and fluconazole. Griseofulvin and ketoconazole are the traditional antifungal agents whose utility for onychomycosis has decreased substantially since the availability of the new oral antifungal agents. In addition, the use of ketoconazole for onychomycosis when long-duration therapy is required has diminished markedly, given the potential for hepatotoxicity.
- The preferred regimens with the new oral antifungal agents are terbinafine (continuous), itraconazole (pulse), and fluconazole (once weekly). The duration of therapy with these agents for fingernail onychomycosis is typically as follows: terbinafine continuous (6 weeks), itraconazole pulse (two pulses), and fluconazole once weekly (6–9 months). The corresponding duration of therapy with these antifungal agents for toenail onychomycosis is 12 or 16 weeks, three or four pulses, and 9–15 months, respectively.
- RCTs have demonstrated that griseofulvin, terbinafine (continuous), itraconazole (pulse and continuous), and fluconazole are effective and safe for the treatment of dermatophyte fingernail and toenail onychomycosis.
- Few RCTs have been conducted for the topical nail lacquer formulations. Although the safety of monotherapy with nail lacquers appears to be good, more rigorous clinical trials need to be done to establish with certainty the efficacy of nail lacquers. Current practice would indicate that the addition of a nail lacquer to an established oral regimen may be a consideration in clinical settings.
- Device-based therapies for onychomycosis have shown promising preliminary results, and several laser systems have been FDA-cleared for this indication based on their substantial equivalence to previously approved laser systems [129]. However, more RCTs with participants with mycologically proved onychomycosis that assess the mycological, clinical, and complete cure rates are needed to be able to compare them with the oral and topical antifungals.
- There are several factors that need to be considered when deciding which agent to prescribe for onychomycosis; these include efficacy, the causative organism, regimen preference (e.g., continuous versus pulse versus once weekly, expected duration of therapy), the safety of the antifungal agent, the patient's medical status, the potential for drug interactions, relapse rates, and the cost of therapy.
- None of the newer oral antifungal agents has been approved for the treatment of onychomycosis in children, in whom the disease occurs much less frequently.

# Tinea capitis

Urbà González

Unit of Dermatology, Clínica Go&Fer, Barcelona, Spain

## Background

### Definition

Tinea capitis (scalp ringworm) is an infection of the scalp skin and hair caused by fungi (dermatophytes) mainly of the genera *Trichophyton* and *Microsporum* [1]. The clinical hallmark is single or multiple patches of hair loss, sometimes with a “black dot” pattern (Figure 44.1), which may be accompanied by signs of inflammation such as scaling, pustules and itching.

### Incidence/prevalence

Tinea capitis is uncommon in adults and is seen predominantly in prepubertal children [2]. It has affected mainly disadvantaged communities in both developing and industrialized nations. Travel and migration have led to changes in the epidemiology of the species of dermatophyte causing tinea capitis.

### Etiology

Tinea capitis is contagious. It can be acquired through contact with people, animals, or objects carrying the fungus [3]. The presence of fungi within the scalp may not be sufficient to result in tinea capitis (carrier state). Approximately eight dermatophyte species are characteristically associated with tinea capitis. Infections due to *Trichophyton tonsurans* predominate from Central America to the USA and in parts of western Europe. *Microsporum canis* infections are mainly seen in South America, Southern and Eastern Europe, Africa, and the Middle East. *Trichophyton mentagrophytes* and *M. canis* are majority pathogenic fungi in China, which mainly come from animals in rural areas or pets in urban areas.

### Prognosis

Tinea capitis is not life threatening in people with normal immunity. Untreated cases cause persistent symptoms, and in some types of tinea capitis (mainly the inflammatory type or kerion) may lead to scarring alopecia (Figure 44.2).

### Diagnostic tests

The clinical diagnosis should be confirmed by mycological examination [4]. The diagnosis of tinea capitis is best undertaken with more than one sampling method: scraping of scalp, scalp massage

brush, toothbrush, or a moistened cotton gauze swab. Microscopy provides the most rapid means of diagnosis and allows treatment to commence, but is not always positive. Culture allows accurate identification of the organism involved and may be positive even when microscopy is negative, but may take up to 4 weeks. Wood's light or filtered ultraviolet light can be used to identify infections that fluoresce under this type of light, such as *M. canis* and *Microsporum audouinii*, but not *T. tonsurans*.

### Aims of treatment

The first aim of treatment is to achieve complete clinical and mycological cure as quickly as possible, with no or minimal adverse effects [5]. Effective short-course therapy is especially desirable in children, because prolonged therapy increases the risk of adverse effects as well as noncompliance. Another goal is prevention of spread to other children from objects, infected animals or children, and from asymptomatic carriers.

### Relevant outcomes

Outcomes are based on resolution of the clinical signs (redness, scaling, edema, and hair loss) and symptoms (itch and pain), and negative mycological data, including microscopy and culture. Complete cure (clinical and mycological cure), cure (clinical or mycological cure), improvement (clinical), and failure (ineffective therapy or worsening) are the most widely used outcomes.

### Methods of search

The methodology of search used for this chapter is an adaptation of the search strategy used in a Cochrane systematic review [6] covering the Cochrane Central Register of Controlled Trials (The Cochrane Library), Medline, and LILACS. Any key randomized clinical trial (RCT) has been included if published by July 2012.

## Systemic antifungal therapy for tinea capitis in children

Griseofulvin has been the most widely used and prescribed treatment for tinea capitis and has served as a standard for the evaluation of any newer agent to be considered for this infection. New drugs used against other fungal infections in adults, such as

Figure 44.1 Tinea capitis.

Figure 44.2 Inflammatory tinea capitis.

ketoconazole, itraconazole, terbinafine, and fluconazole, are being considered more frequently for the treatment of tinea capitis.

## Questions

### In children with tinea capitis, which oral antifungal drug leads to high rates of cure with the fewest adverse events?

#### Griseofulvin

There is moderate RCT evidence that griseofulvin at dosages of 125–500 mg/day (depending on the patient's weight) for 6–8 weeks is effective and safe for the treatment of tinea capitis caused by *T. tonsurans*, *Trichophyton violaceum*, and *M. canis*.

#### Efficacy

Thirteen RCTs compared griseofulvin with other oral antifungals in tinea capitis.

**Different doses** A single-blinded RCT [7] in South Africa (*T. violaceum*) compared two doses of griseofulvin (50 mg/kg) administered 4 weeks apart; weekly doses of griseofulvin (50 mg/kg) for 6 weeks; and daily 6-week course of griseofulvin (10 mg/kg). The mycological cure rates for the groups were 84% (15 of 18), 79% (15 of 19), and 91% (20 of 22), respectively. At 6 months, the mycological cure rates for the three groups remained similar: 92% (11 of 12), 82% (9 of 11), and 95% (16 of 17), respectively. Although the total clinical score fell faster in the daily for 6 weeks group, there was no statistically significant difference in the scores at either 6 weeks or 6 months.

**Versus ketoconazole** Four RCTs were identified. In two RCTs [8,9] (*T. tonsurans*) griseofulvin at dosages of 10–20 mg/kg per day and 250–500 mg/day was compared with ketoconazole 3.3–6.6 mg/kg per day and 200 mg/day for 12 weeks and 6 weeks, respectively. Cure rates in the griseofulvin groups at the end of treatment were 96% and 57.1%, in each study, respectively. A small RCT [10] including 47 children compared griseofulvin 350 mg/day for 6 weeks with ketoconazole 100 mg/day for 6 weeks in inflammatory tinea capitis (*T. mentagrophytes* and *M. canis*). At the end of treatment, 80% and 100% of the children, respectively, had improved clinically, but no mycological data were reported. An RCT with unknown blinding [11] including 63 children (*Trichophyton* spp.

predominated) compared griseofulvin 15 mg/kg per day with ketoconazole 5 mg/kg per day, each given as a single daily dose, and treatment stopped when there was complete cure or after 6 months. After 8 weeks' therapy, 92% of the patients given griseofulvin had complete cure, in comparison with only 59% of the ketoconazole-treated patients. After 12 weeks, 96% of the griseofulvin patients were mycologically cured, in comparison with 74% of the ketoconazole-treated group. Hair sample cultures took significantly longer to become sterile in ketoconazole-treated patients (median 8 weeks) than in griseofulvin-treated patients (4 weeks). However, as other oral azolic antifungals such as itraconazole and fluconazole are available, and as ketoconazole is associated with rare but important hepatic and endocrine adverse events (none of these were noted in the pediatric studies described), ketoconazole has not been considered further as a treatment of choice in children with tinea capitis.

**Versus itraconazole** One RCT [12] in 34 children (*M. canis*) comparing 6 weeks of ultramicrosized griseofulvin 500 mg/day and itraconazole 100 mg/day showed a complete cure rate of 88% for the two drugs after 14 weeks' follow-up.

**Versus fluconazole** Three RCTs comparing fluconazole and griseofulvin were found. The first RCT [13] assessed 100 children (*T. tonsurans* and *T. violaceum*). The children were treated either with fluconazole 6 mg/kg per day for 2–3 weeks or with microsized griseofulvin 20 mg/kg per day for 6 weeks, and the complete cure rates were 82% and 92%, respectively. The second RCT [14] compared 40 children (*T. violaceum*, *Trichophyton verrucosum*, and *M. canis*) treated with 5 mg/kg per day of fluconazole or 15 mg/kg per day griseofulvin for 4 weeks and 6 weeks, respectively. Complete cure was reported for 79% and 76%, respectively. The third study, a three-arm RCT [15] of 880 patients (*T. tonsurans*) compared fluconazole 6 mg/kg per day for 3 weeks followed by 3 weeks of placebo, fluconazole 6 mg/kg per day for 6 weeks, and griseofulvin 11 mg/kg per day for 6 weeks. The complete cure rates were 44.5%, 49.6%, and 52.2%, respectively.

**Versus terbinafine** Eight RCTs were identified. A double-blind RCT [16] compared 140 children from Pakistan (*T. violaceum*). They were treated with either terbinafine (by weight) for 4 weeks or with griseofulvin 6–12 mg/kg per day for 8 weeks. After 12 weeks, 93%

of the terbinafine group was completely cured, in comparison with 80% of the griseofulvin group. A double-blind RCT [17] evaluated 50 children from Peru (*T. tonsurans*). Half were treated with terbinafine according to weight for 4 weeks; the other half received micro-sized griseofulvin according to weight for 8 weeks. After 8 weeks of treatment, complete cure was noted in 76% of the griseofulvin group and in 72% of terbinafine group, but 4 weeks later the complete cure rate increased to 76% in the terbinafine group, while in the griseofulvin group it had fallen to 44%. A large RCT [18] (*T. tonsurans*) compared 8 weeks of griseofulvin suspension 10 mg/kg per day with 4 weeks of terbinafine. The complete cure rates at week 24 were 64% and 67%, respectively. However, there was a trend to better responses in a few cases with *Microsporum* spp. infections with 8 weeks of griseofulvin than with 4 weeks of terbinafine. In another RCT [19] the complete cure rate at the final follow-up visit (week 12) was 74% in the group treated for 8 weeks with ultramicrosized griseofulvin, in comparison with 78% in the group treated with terbinafine for 4 weeks, with no significant differences between *M. canis* and *Trichophyton* spp. infections. Another trial [13] compared 50 patients in each treatment group (*T. tonsurans* and *T. violaceum*). In this trial, terbinafine for 2–3 weeks was compared with micro-sized griseofulvin 20 mg/kg for 6 weeks. The complete cure rate was 94% for the terbinafine group and 92% for the griseofulvin-treated group. Only one RCT [20] assessed medium-term to long-term treatment regimens comparing terbinafine with griseofulvin (*M. canis*). The patients were treated with terbinafine for 6, 8, 10, or 12 weeks, followed by placebo to complete a 12-week treatment phase in a double-blinded regimen, or griseofulvin for 12 weeks using an unblinded regimen. Medium-term treatment (6 or 8 weeks) resulted in a trend towards an increase in the complete cure rate in the griseofulvin group in comparison with the terbinafine group at 4 weeks after the end of treatment. However, long-term treatment (10 or 12 weeks) resulted in the complete cure rates being significantly higher in the griseofulvin group in comparison with the terbinafine group at 4 weeks after the end of treatment. An RCT [21] compared (*Trichophyton* infections) 4 weeks of griseofulvin, 2 weeks of terbinafine, and 4 weeks of terbinafine. The clinical cure rates were 84.2%, 85.2%, and 78.3%, respectively, at week 8 and 100% after 1 year for all agents. Two identical RCTs in children [22] compared once-daily treatment with terbinafine (5–8 mg/kg) or griseofulvin (10–20 mg/kg) for a period of 6 weeks. Complete cure rates were statistically significantly greater for terbinafine compared with griseofulvin in trial 1 (46.23% vs 34.01%) but not in trial 2 (43.99% vs 43.46%). Subgroup analyses revealed that terbinafine was significantly better than griseofulvin for all cure rates (mycologic, clinical, and complete) among patients with *T. tonsurans*. For *M. canis*, mycological and clinical cure rates were significantly better with griseofulvin than with terbinafine.

### Drawbacks

The most common adverse events in the griseofulvin group were nausea, abdominal discomfort and vomiting, headaches, minor disturbances in taste, and pyrexia; almost all were mild or moderate in severity. None of the events was rated as severe. In other studies, no adverse effects or no significant adverse effects were reported.

### Comments

All included studies show that griseofulvin is effective for tinea capitis. The high patient drop-out rate in most of the studies may have masked the improvement in the griseofulvin groups, as those who achieve cure may have less incentive to attend follow-up visits.

It will also have reduced the power to detect a difference between the groups, indicating that griseofulvin may be even more effective. The duration of follow-up varies from study to study (4 weeks–1 year), and only RCTs with long-term follow-up can show the relapse rates, which are very important in determining therapeutic efficacy.

### Implications for practice

There is good evidence to support the use of griseofulvin to treat tinea capitis caused by *T. tonsurans*, *M. canis*, *T. mentagrophytes*, and *T. violaceum*. Overall, griseofulvin is considered to be safe in children. On the basis of the RCTs described, the recommended dosage regimen for children is continuous therapy with tablets or suspension, adjusted according to the patient's weight (10–20 kg: 125 mg/day; 20–40 kg: 250 mg/day; >40 kg: 500 mg/day) for 6–8 weeks, including micro-sized and ultramicrosized preparations. Other advantages of griseofulvin are that it is inexpensive and that the suspension allows accurate dosage in children. Griseofulvin is licensed for the treatment of tinea capitis in most countries.

### Terbinafine

Moderate RCT evidence indicates that terbinafine at dosages of 62.5–250 mg/day (depending on body weight) for 2 weeks in *T. violaceum* infections and for 4 weeks in *T. tonsurans* infections is effective and safe for the treatment of tinea capitis. A few RCTs (limited evidence) suggest that longer therapeutic regimens of 6 weeks may be necessary to treat *Microsporum* spp. infections.

### Efficacy

**Different terbinafine regimens compared** Four RCTs were found. One RCT [23] (*T. violaceum*) compared 1, 2, and 4 weeks of terbinafine therapy, 62.5–250 mg depending on weight. The cure rates were 49% after 1 week of therapy, 61% after 2 weeks, and 67% after 4 weeks. A second RCT [24] compared 1, 2, and 4 weeks of terbinafine, 62.5–250 mg depending on weight, in 79 children and three adults (*T. tonsurans* and *Microsporum ferrugineum*). At week 12, the complete cure rates were 44% in the 1-week therapy group, 57% in the 2-week therapy group, and 78% in the 4-week group. An RCT [25] published in two additional abstracts [26,27] compared 1 week and 2 weeks of terbinafine, 62.5–250 mg depending on weight. At week 12 of follow-up, in *Trichophyton* spp. infections the complete cure rate was 44.4% with 1 week of therapy and 64% with 2 weeks, but acceptable cure rates in *M. canis* infection were achieved only after an additional 4 weeks of treatment. An RCT [28] including 107 children (*M. canis*) compared 1, 2, and 4 weeks of terbinafine, 125–250 mg/day depending on weight. At week 12, the mycological cure rate was 46% with only 1 week of therapy, 53% with 2 weeks, and 69% with 4 weeks. In another RCT [29] that compared different regimens of terbinafine at dosages of 3–6 mg/kg per day for 1, 2, or 4 weeks, the complete cure rates were 38%, 46%, and 48% for the 1-week, 2-week, and 4-week arms, respectively. Another RCT [30] assessed the efficacy of the standard dose of terbinafine in comparison with double doses of terbinafine, both given in a pulsed protocol (1 week on, 3 weeks off) in the treatment of *Microsporum* spp. tinea capitis. There were no statistical differences in the cure rates between standard and double-dose pulsed therapy at week 20; the standard-dose group achieved a complete cure rate of 60.8%, while the double-pulse group reached 68.4%.

Seven RCTs compared terbinafine with other oral antifungals in tinea capitis.

**Versus griseofulvin** Eight RCTs were identified and they have been commented in the previous section on griseofulvin.

**Versus itraconazole** One RCT [31] compared (*T. violaceum*) 2-week courses of terbinafine 62.5–250 mg and itraconazole 50–200 mg (both depending on weight). Twelve weeks after the start of treatment, 78% and 86% of the patients were completely cured in the terbinafine and itraconazole groups, respectively. Another RCT [13] compared (*Trichophyton* species) itraconazole and terbinafine in a 2–3-week course of therapy; the complete cure rates at 12 weeks were 94% for the terbinafine group and 82% for the itraconazole group.

**Versus fluconazole** The same RCT [13] analyzed the efficacy of fluconazole for 2–3 weeks in comparison with terbinafine, dosed according to weight for 2–3 weeks. The complete cure rates were 82% in the fluconazole arm and 94% in the terbinafine arm, similar to the results for griseofulvin.

### Drawbacks

Tolerability was generally reported as good, with no or few mild to moderate adverse events of uncertain relationship or unrelated to the drug: headache, fatigue including somnolence, nausea, dyspepsia and abdominal pain, mild constipation, pruritus, urticaria, labial edema, moderate loss of appetite, mild diarrhea, mild and moderate partial loss of taste (recovered within 8 weeks), coughing and fever, raised hepatic enzymes, raised triglycerides, eosinophilia, leukocytosis, and neutropenia.

### Comments

An RCT [32] of a group of New Zealand patients (*M. canis*) was excluded because it did not provide separate clinical and mycological data for each study group. The manufacturer of terbinafine has been involved in most of the RCTs. The definition of cure varies from study to study; some investigators follow microbiological findings, while others place greater emphasis on clinical response. High drop-out rates in some studies may artificially decrease the response rate, as those who are cured may be lost to follow-up.

### Implications for practice

There is good evidence to support the use of terbinafine for treating *T. tonsurans* tinea capitis in children, and fair evidence to support its use in *M. canis* tinea capitis. Terbinafine has an advantage over griseofulvin in that it produces good results in a shorter time, making patient compliance less of a problem. An important disadvantage is that it is available only in tablet form; there is no suspension. It is also much more expensive than griseofulvin. According to the RCTs, the recommended regimen in children with tinea capitis is continuous therapy once daily for 4 weeks, with dosage according to body weight: 62.5 mg/day for children weighing 10–20 kg; 125 mg/day for those weighing 20–40 kg; 250 mg/day for those weighing over 40 kg. Analysis of the respective studies showed that treatment duration of 4 weeks is clearly better than 1 week and 2 weeks. *M. canis* infections may require treatment for 6–8 weeks (griseofulvin is likely to be superior to terbinafine for the cases of infections by *Microsporum* species). Terbinafine is not licensed for this indication in children in some countries.

### Itraconazole

Limited RCT evidence shows that oral itraconazole at dosages depending on the patient's weight (<20 kg: 50 mg/day; >20 kg: 100 mg/day) for 2–6 weeks is effective and safe for tinea capitis

caused by *T. violaceum* (2 weeks of treatment) and *M. canis* (6 weeks of treatment). Only observational data suggest that itraconazole may be effective against *T. tonsurans* infections.

### Efficacy

Three RCTs compared itraconazole with other oral antifungals.

**Versus griseofulvin** See section on griseofulvin.

**Versus terbinafine** See section on terbinafine.

**Versus fluconazole** In an RCT [13], itraconazole in patients with *Trichophyton* infections, at a dosage of 5 mg/kg per day daily for 2–3 weeks, was compared with fluconazole; the complete cure rates were 82% in both groups.

### Drawbacks

Transient gastrointestinal side effects are the most frequently reported, and rarely a reversible increase in serum aminotransferase. Other less frequent reported side effects are urticaria, headache, and “tired legs.”

### Comments

The methods of randomization and blinding were not clearly described in some RCTs. Only one of the RCTs [12] was funded by the manufacturer of itraconazole. More, but less reliable, information is available from uncontrolled studies, but additional RCTs comparing itraconazole with other antifungals are clearly needed.

### Implications for practice

There is fair evidence to support the use of itraconazole for the treatment of tinea capitis caused by *M. canis*, *T. violaceum*, and *T. tonsurans* in children. On the basis of the available evidence, the recommended dosage for itraconazole for tinea capitis in children is 100 mg/day or dose adjusted to body weight, for 6 weeks in *M. canis* and for 2 weeks in *T. violaceum* infections. Uncontrolled studies suggest that shorter or pulse regimens may also be useful.

### Fluconazole

Limited evidence suggests that fluconazole continuously at 6–8 mg/kg per day for 3 weeks or intermittently at 6–8 mg/kg per week for 4–8 weeks is effective and safe for treating *T. tonsurans* and *M. canis* tinea capitis in children.

### Efficacy

**Different fluconazole regimens compared** A small RCT [33] compared various dosages of fluconazole (1.5, 3.0, and 6 mg/kg per day) for 20 days in the treatment of *T. tonsurans* tinea capitis. Complete cure rates were 25% in the 1.5 mg group, 60% in the 3 mg group, and 89% in the 6 mg group.

Three RCTs compared fluconazole with other systemic antifungals for tinea capitis.

**Versus griseofulvin** See section on griseofulvin.

**Versus terbinafine** See section on terbinafine.

**Versus itraconazole** See section on itraconazole.

### Drawbacks

Only mild, reversible gastrointestinal complaints and asymptomatic and reversible elevated liver function tests were noted in an RCT. No adverse effects were reported in some trials.

### Comments

Studies are needed in order to compare fluconazole with other antifungals and to determine the proper dosing and duration of therapy.

### Implications for practice

There is some evidence to recommend a dosage regimen with fluconazole for tinea capitis in children. Observational studies suggest that continuous 6 mg/kg per day for 3 weeks or intermittent 6–8 mg/kg per week for 4–8 weeks may be effective. Fluconazole is not licensed for this indication in children in some countries.

### What are the effects of topical treatment of tinea capitis in adults and children?

Adjunctive topical therapy has been used together with oral antifungal treatment to eradicate the fungi from the infected site, decrease spread to other people, and speed the cure. Various topical agents are available for adjunctive therapy.

### Shampoos

There is moderate RCT evidence that the addition of biweekly shampooing with selenium sulfide substantially reduces the period of active shedding. However, some evidence indicates that topical treatment is not useful for tinea capitis.

### Efficacy

An RCT [34] reported that 75% of griseofulvin-treated patients with uncomplicated *T. tonsurans* tinea capitis had sterile hair sample cultures 4 weeks after initiation of griseofulvin. By contrast, 94% of patients who received griseofulvin together with biweekly selenium sulfide shampoos had sterile hair cultures at 4 weeks. Another RCT [35] of 54 patients receiving griseofulvin 15 mg/kg per day for *T. tonsurans* tinea capitis compared selenium sulfide 2.5% lotion or 1% shampoo with a bland, unmedicated shampoo. Patients were observed every 2 weeks until they were clinically and mycologically cured. The selenium sulfide products were statistically superior to the unmedicated shampoo with regard to the time required to eliminate shedding and viable fungi. However, no difference was noted between the two selenium products. One RCT [36] compared selenium sulfide shampoo 1% and ciclopirox shampoo 1% twice a week as adjuncts to an 8-week course of ultramicronized griseofulvin dosed at 10–12 mg/kg per day. Selenium sulfide shampoo 1% and ciclopirox shampoo 1% were equally effective as adjunctive treatments for tinea capitis in children in our study. Overall, 90.9% of treated children demonstrated mycological cure.

### Soap

An RCT [37] assessed the clinical efficacy of the antimicrobial agent triclosan in bar soap in comparison with regular soap against selected superficial dermatomycoses in Tanzanian schoolchildren. There was no significant difference between the active and placebo groups during follow-up after 2 months for any of the four forms of dermatomycoses.

### Cream/ointment

One RCT [38] was conducted in a region of Africa in which griseofulvin is not generally available. It compared 6 weeks of miconazole cream with 6 weeks of Whitfield's ointment (6% benzoic acid plus 3% salicylic acid) in *T. violaceum* and *M. audouinii* tinea capitis and found no significant cure rates.

### Drawbacks

No adverse events were reported.

### Comments

RCTs of adjunctive therapy were described as randomized, but did not adequately describe the method and were not blinded.

### Implications for practice

There is some evidence to support the use of adjunctive topical therapy for tinea capitis with antifungal shampoos (for example, 1% selenium sulfide shampoo) to reduce the time of cure and to decrease the spread of infectious fungi to other persons. There is also some evidence not supporting the exclusive use of topical agents to treat tinea capitis.

### In children with inflammatory tinea capitis (kerion), does an oral antifungal plus a corticosteroid lead to faster cure and complete hair regrowth than an oral antifungal alone?

#### Corticosteroids

Moderate RCT evidence indicates that the use of oral or intralesional corticosteroids as adjunctive therapy with griseofulvin for inflammatory tinea capitis (kerion) does not lead to additional or faster improvement.

### Efficacy

Three RCTs showed no evidence that the use of intralesional [39] or oral [40,41] corticosteroids as adjunctive therapy with oral griseofulvin in inflammatory tinea capitis (kerion) results in additional or faster improvement of kerion. One RCT [39] of 30 children (*T. tonsurans*) showed that intralesional injection of corticosteroid combined with oral griseofulvin is no better than griseofulvin alone for treatment of kerion, and found no significant differences in the time to negative culture, time of onset of new hair growth, complete regrowth of hair, or time to scalp clearing. In this study, all patients were instructed to shampoo their hair with 1% selenium sulfide twice weekly for 3 weeks. Two small RCTs [40,41] using oral corticosteroids showed no additional benefit in terms of improvement, reduction in the severity of clinical signs, or pathogen eradication.

### Drawbacks

No adverse events were noted. In particular, none of the patients had post-therapy alopecia, permanent scarring, or biochemical evidence of hepatic dysfunction.

### Comments

Whether larger doses of steroid might be effective remains unknown. In an RCT, scaling and pruritus were eliminated more quickly in the group that used oral erythromycin and oral prednisone in addition to griseofulvin, but the authors considered that this may have been due to the smaller volume of the kerions in this group rather than the effects of therapy, so that the patients became symptom free sooner.

### Implications for practice

The addition of corticosteroids to oral antifungals is unlikely to be useful. There is some limited evidence questioning the use of oral or intralesional corticosteroids as adjunctive therapy for inflammatory tinea capitis (kerion).

## What strategies are best for reducing spread and reinfection in tinea capitis in adults and children?

Carrier state is found in individuals with no signs or symptoms of tinea capitis, but from whom positive cultures from the scalp can be isolated. Strategies for management of the carrier state include preventive treatments such as fungicidal shampoos, decontamination of objects that come into contact with the scalp, education programs for children to avoid sharing of objects that can spread tinea capitis to others (such as caps, combs, and toys), and shaving of hair. There is no RCT evidence regarding the optimal management of symptom-free carriers. No RCTs were found concerning the impact of strategies for management of the asymptomatic carrier state.

## Implications for practice

The effectiveness is unknown. Although it is agreed that decontamination of objects that come into contact with the scalp, education programs for children, and avoidance of sharing of objects can reduce the spread of fungal infections, there is no good evidence to support such decontamination procedures. No evidence supports the regular use of antifungal shampoos in controlling the carrier state of populations at risk. Povidone iodine shampoo may be the most suitable for prophylaxis [42].

### Key points

#### Systemic antifungal therapy for tinea capitis in children

- RCT evidence suggests that griseofulvin for 6–8 weeks is effective and safe for tinea capitis.
- The best evidence available also suggests that terbinafine, itraconazole, and fluconazole can cure most patients with tinea capitis with a shorter course of therapy. All these drugs may be preferred because shorter treatment durations may improve treatment adherence, although they may be more expensive. Not all these treatments are available in pediatric formulations, but they have good safety profiles in children. However, there is not enough evidence on the use in children with *Microsporum* infections.
- RCT evidence indicates that terbinafine for 4 weeks is effective and safe for treating *Trichophyton* spp. tinea capitis. Some evidence suggests that longer therapeutic regimens of 6 weeks are necessary to treat *Microsporum* spp. infections.
- Some RCT evidence suggests that oral itraconazole for 2–6 weeks and fluconazole for 3–6 weeks are effective and safe for treating tinea capitis in children.
- Regional as well as dermatophyte species variation may play an important role in the response rate, and may determine what dosage regimens are recommended. Resistance to antifungals could be a major concern in some areas.

#### Adjunctive therapy for tinea capitis in adults and children

- Some RCT evidence suggests that antifungal shampoos can reduce the period of active shedding in patients treated with oral antifungals.
- There is not enough evidence to say whether the addition of oral steroids to antifungal agents improves the resolution of inflammatory tinea capitis.

#### Strategies to reduce spreading and reinfection in tinea capitis

- There is insufficient evidence suggesting that antiseptic shampoos can reduce spread from carriers.
- No RCT evidence exists regarding the optimal management of symptom-free carriers.

# Deep fungal infections

Roderick J. Hay

Department of Dermatology, Kings College Hospital, London, UK

## Introduction

Deep fungal infections or mycoses comprise a group of diseases that spread within the subcutaneous tissues (subcutaneous mycoses) or predominantly involve deeper structures, including blood and bone marrow, along with other organs such as the lung and the liver (systemic mycoses). They include a number of different diseases (Table 45.1).

Involvement of the skin in subcutaneous mycoses is usually secondary to direct spread from adjacent sites of infection – as in mycetoma, where sinuses from deep abscesses reach the skin surface. The skin is usually breached during the process of infection, and the organisms are often found in the environment with which the patient has contact.

In the case of the systemic mycoses, skin involvement is less common, but may occur through bloodstream spread, in which the skin lesions are a consequence of dissemination and the formation of active infective foci in the dermis. The lung is usually the portal of entry in infections such as histoplasmosis, known as the endemic respiratory mycoses. Rarely, the skin is the portal of entry in systemic fungal infections, and the clinical course in such cases may be more benign, sometimes responding to minimal therapy. This pattern of infection, in which there is local inoculation followed by local lesions and regional lymphadenopathy, is referred to as the cutaneous chancriform syndrome. By contrast, fully developed and widely disseminated disease spreading via fungemia to affect the skin is often fatal. Infections with certain fungi such as *Talaromyces marneffe* are more likely to result in skin lesions; in the latter infection, over 70% of cases associated with acquired immune deficiency syndrome (AIDS) present with skin lesions. An important subset of systemic mycoses is referred to as the opportunistic mycoses, because there is always an underlying abnormality such as neutropenia or AIDS. Systemic candidosis and aspergillosis belong to this group. Skin involvement is rare and is usually the result of bloodstream spread.

This chapter is largely concerned with the subcutaneous mycoses. The systemic mycoses are, by definition, severe internal infections, and a discussion of their management is beyond the scope of a dermatological work. In addition, there are no clinical studies

directly relevant to the cutaneous manifestations of the systemic diseases, with the exception of a debate about the relevance of direct cutaneous invasion in their pathogenesis.

Subcutaneous infections are rare and are generally confined to developing countries. There are few well-organized clinical studies in these infections, and randomized double-blind controlled trials are exceedingly rare.

The evidence search for this chapter is based on the Cochrane Central Register of Controlled Trials (version 3, 2007) and my own collection of studies and personal contacts in the field. Most drugs used for these infections have been developed to treat other mycotic infections, and their application to deep mycoses is based on individual cases or case clusters. Each of the subcutaneous mycoses is dealt with separately.

## Mycetoma

### Definition

Mycetoma is a subcutaneous infection caused by either fungi (eumycetoma) or actinomycetes (actinomycetoma) (Figure 45.1). The focus of infection is the subcutaneous tissue, including subcutaneous fat. The hallmark of the infection is that the microorganisms involved form into clusters of filaments called grains, which are surrounded by a dense neutrophil response, forming an abscess. These abscesses subsequently discharge onto the skin surface via draining sinuses, but may affect underlying bone, resulting in osteomyelitis. Infective organisms are implanted into the skin, usually following a thorn injury [1].

### Incidence/prevalence

Mycetoma is an uncommon infection (Figure 45.1), and there are no community-based data on its prevalence. Information on the worldwide incidence is based on an old study conducted by postal questionnaire in which interested departments (133) submitted data on numbers of cases occurring between 1940 and 1960. The results were published in 1963 [2], and indicate that certain countries such as Sudan and Mexico had the highest numbers of cases.

Table 45.1 The deep mycoses.

Disease	Pathogens
<i>Subcutaneous mycoses</i>	
Mycetoma	<i>Madurella mycetomatis</i> , <i>M. grisea</i> (fungi) <i>Nocardia</i> spp., <i>Streptomyces somaliensis</i> (actinomycetes) and others
Chromoblastomycosis (chromomycosis)	<i>Fonsecaea pedrosoi</i> , <i>Cladophialophora carrionii</i> , and others
Sporotrichosis	<i>Sporothrix</i> spp.
Lobomycosis	<i>Lacazia loboi</i> (previously called <i>Loboia loboi</i> )
Subcutaneous zygomycosis	<i>Basidiobolus</i> or <i>Conidiobolus</i> spp.
<i>Systemic mycoses</i>	
<i>Endemic respiratory infections</i>	
Histoplasmosis	<i>Histoplasma capsulatum</i> var. <i>capsulatum</i>
African histoplasmosis	<i>H. capsulatum</i> var. <i>duboisii</i>
Blastomycosis	<i>Blastomyces dermatitidis</i>
Coccidioidomycosis	<i>Coccidioides immitis</i>
Paracoccidioidomycosis	<i>Paracoccidioides brasiliensis</i>
Infections due to <i>Penicillium marneffei</i>	<i>Talaromyces marneffei</i>
<i>Opportunistic infections</i>	
Systemic candidosis	<i>Candida albicans</i> , <i>C. tropicalis</i> , <i>C. glabrata</i>
Aspergillosis	<i>Aspergillus fumigatus</i> , <i>A. flavus</i> , <i>A. niger</i>
Cryptococcosis	<i>Cryptococcus neoformans</i>
Mucormycosis (invasive zygomycosis)	Species of <i>Absidia</i> , <i>Rhizopus</i> , and <i>Rhizomucor</i>
Others	Infections due to <i>Fusarium</i> , <i>Trichosporon</i>

However, some countries such as India, in which the disease is endemic, did not participate, so that the data are incomplete.

Etiology and risk factors

Infections follow traumatic implantation of contaminated material from the environment. Because there are no known animal models, the method of infection is unknown. There are also no known risk factors apart from rural occupation. One report suggested that there was a higher incidence of diabetes mellitus in those with the disease, but it did not include appropriate controls, and the observation has not been substantiated elsewhere [3].

Prognosis

There are no studies indicating the prognosis of this infection. Most patients have been found to have some morbidity, usually resulting from limb deformity, but death has been known to occur in cases in which the infection affects the scalp or chest wall.

Treatment aims

The primary aim in the treatment of mycetoma is to eradicate the infection and thereby halt the progression of deformity. This is possible in the case of actinomycetomas, which are bacterial infections;

Figure 45.1 A eumycetoma infection.

however, there is insufficient evidence to support a particular regimen of treatment for eumycetomas, although individual responses have been recorded for ketoconazole, itraconazole and terbinafine, and amphotericin B [4]. Generally, the response rates amongst eumycetoma infections to chemotherapy are low and unpredictable. Increased chances of cure are associated with longer treatment duration, whereas size (above 5 cm diameter ) and the use of combined surgery and medical treatment are indicators of likely treatment failure [5]. In eumycetoma, a secondary objective is to slow the course of the disease, thus delaying the time when amputation becomes necessary. Amputation provides a radical cure.

Outcomes

Outcomes range from recovery to slowing of the disease progress. Mycetoma is rarely fatal, and the main problems even in extensive disease are deformity and disability. In a few cases in which the disease affects areas close to vital structures, such as the chest wall or cranium, the outcome is fatal.

The main approaches to management are therefore chemotherapy, combined in some cases of eumycetoma with surgery. Surgery itself may remove tissue from weight-bearing areas in which the lack of support may result in pain and further disability.

Can mycetoma be treated successfully?

Efficacy

The usual treatments are chemotherapy for actinomycetomas and surgery and/or chemotherapy for eumycetomas. I have been unable to find any systematic reviews of treatment, and there are no controlled clinical trials. Good responses to drugs such as sulfonamides and sulfones, as well as co-trimoxazole, have been reported in the management of actinomycetomas [6], and the addition of amikacin has been evaluated in an open study [7]. Treatment of eumycetoma with chemotherapy produces unpredictable results [4] and recovery is unusual. Radical surgery, including limb amputation, is curative in most cases.

Drawbacks

There are also no studies reporting side effects of therapy in the specific case of mycetoma. The adverse events related to azoles such as ketoconazole and itraconazole are symptomatic hepatitis (rare with itraconazole), toxic epidermal necrolysis, and drug interactions with some common medications such as terfenadine, astemi-

zole, ciclosporin, tacrolimus, digoxin, and statins, interaction with the latter resulting in rhabdomyolysis.

### Comments

Mycetoma is a rare disease caused by more than 10 different micro-organisms distributed throughout much of the developing world. A new generation of clinical trials to provide the foundation for an evidence-based review of treatment remains unlikely and could only be achieved with a coordinated multinational approach.

### Implications for clinical practice

Treatment is likely to continue to be based on anecdotal evidence of the efficacy of different regimens.

#### Key points: mycetoma

- Treatment of actinomycetoma usually depends on two drugs, such as co-trimoxazole plus rifampicin. The latter is given for up to 6 months, while the other medication is continued until clinical recovery.
- Sulfonamides or sulfones can be used instead of co-trimoxazole, and streptomycin instead of rifampicin [4,7].
- Another proposed two-step regimen based on a small case series involves an intensive phase of therapy with penicillin, gentamicin, and co-trimoxazole for 5–7 weeks, followed by maintenance therapy with amoxicillin and co-trimoxazole [8].
- A successful outcome of treatment is less likely for eumycetomas. Therapy is therefore based on the premise of control of the infection by suppression of the disease, using fluconazole [9], itraconazole [10,11] or terbinafine [12], voriconazole [13] plus amphotericin B [4]. Patients are followed over years.
- Where necessary, surgery is used to supplement the medical approach for slowing eumycetomas. Indications for amputation are advancing disease threatening the whole limb (for example, involvement of the femur) and severe pain.
- Arterial perfusion with amphotericin B has also been tried for eumycetoma, with variable success rates [14].

## Sporotrichosis

### Definition

Sporotrichosis is a subcutaneous and systemic infection caused by *Sporothrix* species, such as *S. schenckii*, a dimorphic fungal pathogen found in leaf and plant debris. The subcutaneous variety described here presents with solitary or lymphangitic nodules or ulcers on exposed cutaneous sites.

### Incidence and prevalence

This is an uncommon infection and there are few data on its prevalence. A problem in estimating the exposure is that the frequency of subclinical infection is unknown. Using the crude antigen sporotrichin, it appears that many of the local unaffected population in endemic areas have positive reactions to the skin test (for example, 22%) [15], but it is not clear if this is the result of exposure to *Sporothrix* spp. or to cross-reactive fungal species.

By plotting the spread of cases, it appears that sporotrichosis is mainly seen in the tropics and subtropics and in parts of the USA. Before the 1940s, it was regularly seen in Europe, where it is now uncommon.

It is clear that cutaneous sporotrichosis may occur in the form of isolated cases or in case clusters associated with exposure to a common source of infection, such as straw used in packing [16]. A major and continued outbreak was associated with contaminated pit props used in mines in South Africa. In addition, it appears that there are areas termed hyperendemic in parts of the world – for example, Guatemala, Mexico, Brazil, and Peru. In Brazil, a major risk factor for infection appears to be spread from infected cats [17].

### Etiology and risk factors

Infections follow traumatic implantation of infected material from the environment, although it is not clear whether this is always followed by clinical disease. Risk factors include occupation – for example, miners, flower workers, those using plant material for packing, and armadillo hunters have all been described as being at risk from exposure.

### Prognosis

There are no studies to show whether there is spontaneous resolution, but this seems possible. There is clearly a wider spread of cutaneous lesions in patients with AIDS, and there is a risk of internal dissemination from skin lesions in such cases. Rare cases of systemic sporotrichosis usually appear to have arisen independently of skin injury and are thought to have followed inhalation and subsequent dissemination from the lung.

### Treatment aims

The aim of treatment is cure of the disease. Generally, full recovery is achievable.

### What is the best treatment for sporotrichosis?

#### Efficacy

The classic treatment of sporotrichosis is a saturated solution of potassium iodide. It is started at a dosage of 1 mL three times daily, and the dose is increased dropwise until 4–6 mL is being administered three times daily [18,19]. The solution is often associated with side effects such as nausea, vomiting, and swelling of the salivary glands. However, terbinafine, itraconazole, and fluconazole have recently been used with some success in this infection [19–22].

Saturated potassium iodide is still widely used because it is cheap. One unblinded randomized comparative study of 57 people with culture-confirmed sporotrichosis showed that there was no advantage in splitting the dose of potassium iodide into three and that a single daily dose was as effective and no more toxic, with cure rates of around 89% in both groups after 45 days of follow-up [23]. The alternative therapies are itraconazole 100–600 mg daily and terbinafine 250 mg daily. Itraconazole given for up to 36 months is recommended in a guideline for cutaneous sporotrichosis by the American Infectious Disease Society [24]. The efficacy of itraconazole is mainly supported by open studies [20,21], and there are fewer studies of terbinafine [12]. A study comparing continuous (100 mg daily) versus pulsed (200 mg twice daily for 1 week in every 4 weeks) itraconazole showed no significant difference between the two treatment regimens [25]. Patients with lymphocutaneous sporotrichosis respond slower to itraconazole than those with the fixed pattern of infection [21]. However, a recent trial comparing terbinafine in two dose forms, 1000 mg versus 500 mg daily, has demonstrated better results (87% vs 52% clinical cure) and fewer relapses up to 24 weeks after the end of treatment [26]. A bidirectional cohort study in Brazil found that 250 mg terbinafine daily was equally effective compared with 100 mg itraconazole, although in

a few individual patients the dose of both drugs had to be doubled [27]. One study of fluconazole 200–800 mg daily [22] produced a cure in 10 of 14 patients (71%) with lymphocutaneous sporotrichosis.

Other proposed methods of treatment include liquid nitrogen as cryotherapy [28]. I have been unable to find any systematic reviews of treatment.

### Drawbacks

There are few studies reporting side effects of therapy specific for sporotrichosis, and readers are referred to references to itraconazole and terbinafine. Potassium iodide causes other specific side effects, such as sickness, vomiting, hypersalivation, and salivary gland swelling. These side effects are common (affecting around half of the trial participants in the one study described above [23]) and usually mild.

### Comments

There are opportunities for controlled studies of therapy in sporotrichosis, even though the disease is uncommon in many areas.

### Implications for clinical practice

Given the absence of randomized controlled studies that evaluate different treatment approaches for sporotrichosis, the current recommendations are based mainly on experience and open studies.

#### Key points: sporotrichosis

- The main treatments in use are saturated potassium iodide solution and itraconazole.
- The disadvantage of potassium iodide is the high frequency of side effects, but the preparation is cheap.
- Fluconazole and terbinafine are alternatives, both of which show efficacy.
- Itraconazole appears to be effective, but is used for similar long treatment periods to those used with potassium iodide. More comparative studies with terbinafine and fluconazole are needed.

## Chromoblastomycosis

### Definition

Chromoblastomycosis is a subcutaneous infection caused by a number of different fungi, such as *Cladophialophora carrionii* and *Fonsecaea pedrosoi*; a less common cause is *Phialophora dermatitidis*. The infection starts in the subcutaneous tissue or dermis, and this is followed by progressive enlargement of cutaneous plaques, which are usually either verrucose or plaque-like, with central scarring. The organisms can be found in skin scrapings or biopsies as small pigmented cells, often divided by a cross-wall.

### Incidence and prevalence

This is an uncommon infection and there are no data on its prevalence. The disease is therefore known by clinical anecdote and reported cases. The endemic zone includes the tropics, particularly the humid zones; countries such as Costa Rica, Brazil, and Madagascar probably have the largest number of cases [29].

### Etiology and risk factors

Infection follows traumatic implantation of material from the environment. Fungi such as *Fonsecaea* species can be isolated from

leaves and plant material. Although agricultural workers appear to be most at risk, there are no multicenter studies evaluating this issue [29].

### Prognosis

There are no studies indicating the prognosis of this infection. However, a small proportion of patients (5%) may progress to squamous carcinoma of the skin in the affected area.

### Treatment aims

The primary aim of treatment is complete recovery [29]. This is not always achievable in advanced disease. A secondary aim is prevention of complications such as squamous cell carcinoma.

### Outcomes

As stated above, full recovery is not always achievable, although in early cases full recovery can be expected.

### What is the best treatment for chromoblastomycosis?

#### Efficacy

The treatment of chromoblastomycosis is complex. I have not found any controlled clinical studies of therapy. It is not clear, however, whether a single drug can cure extensive disease. Most of the treatment failures appear to occur when the infection covers a wide area.

The main treatments currently in use are itraconazole and terbinafine. Itraconazole has been used in doses of 100–400 mg daily with good results, particularly in early cases [30,31]. Terbinafine has been used in doses of 250 mg daily, also with good responses [32,33]. There is less experience with fluconazole, although it has been cited as an effective therapy [34]. There is no clear evidence that there are different responses to the two agents. In unresponsive cases, alternatives include combination therapy with amphotericin B and flucytosine [35], or itraconazole and flucytosine [36], or itraconazole and fluconazole [31]. Physical methods such as heat therapy and cryotherapy have also been used. Heat therapy involves application of heat-retaining materials to the lesions, repeated daily or less frequently over a number of weeks [36,37]. Prolonged treatment with repeated episodes of cryotherapy has been shown to lead to the resolution of lesions without relapse during a 3-year follow-up period in 41% of patients [38]. Itraconazole has also been used in a pulsed format [39] and in combination with physical methods. One comparative trial of 12 patients with histologically confirmed chromoblastomycosis evaluated the benefit of cryotherapy in addition to itraconazole [40]. The authors suggested that itraconazole can be used initially to reduce the size of lesions, with cryotherapy being given to the residual lesion. Topically applied ajoene under occlusion has been compared with topical fluorouracil (5-FU) in the management of chromoblastomycosis due to *C. carrionii*. Both were reported to be effective, with over 74% cure rates. There was a higher risk of post treatment scarring in the patients receiving the 5-FU [41].

### Drawbacks

The potential risks of treatment with terbinafine and itraconazole are discussed elsewhere in this volume. Flucytosine is an oral/intravenous drug. Potential side effects include nausea, diarrhea, and headache, and dose-dependent bone-marrow suppression. The latter occurs when plasma flucytosine levels exceed 100 mg/mL. The dose of flucytosine should be reduced in patients with renal impairment (there is a useful guide in the packet insert), and it is

difficult to obtain in many parts of the world where this disease is endemic. Full blood and platelet counts should be followed during therapy; electrolyte and urea levels are also indicative of impending renal impairment. It is possible to monitor serum levels of flucytosine, reducing the dose if necessary. The optimum level is 40–60 mg/mL.

### Comments and implications for clinical practice

The best approach to treatment in most cases is to use terbinafine or itraconazole. When the disease is extensive, combination therapy with flucytosine plus itraconazole is of potential use.

### Other subcutaneous mycoses

The other subcutaneous mycoses are even rarer and occur in remote areas. It is not possible to provide an evidence base for their diagnosis and treatment. They include the subcutaneous mucoromycete infections due to *Conidiobolus* and *Basidiobolus* species, which cause woody swellings infiltrated by the strap-like fungi that cause the infections, fibroblasts, and eosinophils.

### Systemic mycoses

The systemic mycoses occasionally exhibit direct skin invasion following infiltration of organisms, or indirect skin manifestations such as erythema nodosum or multiforme, which are thought to develop following immune complex deposition. These are discussed briefly below.

#### Key points: chromoblastomycosis

- Chromoblastomycosis is caused by a number of different environmental fungi that are implanted through the skin.
- On the basis of several case series, most infections probably respond to terbinafine or itraconazole.
- Physical therapies such as cryotherapy and heat treatment have also been used and may confer additional benefit to drug therapy.
- Flucytosine plus itraconazole may be of value in people who have extensive disease.

### The endemic mycoses

Skin involvement is seen as a consequence of one of three different mechanisms: direct penetration, bloodstream spread from a deep focus, and as an immunological reaction to primary, often respiratory, infection. In the latter instance, the skin lesions most commonly seen are erythema nodosum or multiforme.

In the endemic mycoses, the usual portal of entry is the lung. Direct entry via inoculation has been proposed in the case of some mycoses, such as paracoccidioidomycosis caused by *Paracoccidioides brasiliensis*, in which mucocutaneous lesions are common (for example, around the nose or mouth). The incidence of pulmonary disease in *P. brasiliensis* infection, even in the presence of skin lesions, is much higher in the endemic areas, suggesting that widespread subclinical exposure is most likely acquired through the airborne route. The demonstration of dissemination to mucocutaneous areas following fungemia in animal models and the existence of subclinical pulmonary forms of disease support the view that skin lesions of paracoccidioidomycosis result from dissemination to skin from the lung. This is likely to be true of most cases of systemic endemic mycosis.

### Opportunistic mycoses

The opportunistic mycoses include infections due to *Candida*, *Aspergillus*, and zygomycete fungi of the genera *Rhizopus*, *Rhizomucor*, and *Absidia*, amongst others. Infection affecting the skin is uncommon, and these infections seldom present to a dermatologist; any skin involvement has to be set against the background of widespread and life-threatening disease. These infections often occur in patients with severe defects of either neutrophil numbers or function, such as recipients of stem cell transplants and cancer patients. *Candida* also affects seriously ill patients in intensive care or after abdominal surgery, neonates, and after prolonged intravenous feeding. Isolated cases of cutaneous aspergillosis and zygomycosis have been recognized following abrasion at a specific site. Disseminated candidosis rarely affects the skin either in neutropenic individuals or in intravenous drug abusers. Systemic *Cryptococcus* infection has been extensively evaluated in at least 16 randomized controlled trials in people with AIDS.

Patients with deep systemic mycoses rarely present directly to the dermatologist. However, there is an extensive literature on the treatment of disseminated fungal infection, and through the involvement of organizations such as the Mycosis Study Group (USA), the UK Medical Research Council (MRC), and the European Organization for the Research and Treatment of Cancer (EORTC) a number of ground-breaking controlled clinical trials have been undertaken independently of, but with full cooperation from, the pharmaceutical industry. These have focused on various forms of treatment, from prevention to specific therapy or empirical therapy.

One form of systemic mycosis that a dermatologist may be called to see is primary cutaneous cryptococcosis. Proving the existence of genuine isolated cutaneous forms of disseminated fungal disease following local trauma and possible direct inoculation, in comparison with localized lesions following bloodstream spread, has been difficult, but the concept is important as it has implications for treatment (for example, the use of smaller doses that might be effective in localized forms of infection). The problem is well encapsulated by consideration of primary cutaneous cryptococcosis.

Cases of primary cutaneous cryptococcosis are rarely reported, and the evidence for direct entry through the skin is often poorly substantiated and generally anecdotal. There are no clinical signs that are likely to provide an accurate indicator that the infection has developed as a result of cutaneous inoculation [42]. The evidence for its occurrence, therefore, can be summarized as follows:

- The first sign of infection is the development of an isolated skin lesion.
- There are no other signs or symptoms of disease, apart from regional lymphadenopathy.
- There is no circulating cryptococcal antigen or antigen in the cerebrospinal fluid, measured by conventional tests such as the cryptococcal antigen enzyme-linked immunosorbent assay.
- Oral antifungal therapy with fluconazole or itraconazole is effective.

An alternative interpretation for the development of cryptococcal skin lesions was described some time ago by Noble and Fajardo [43] and was based on the subsequent identification of another focus of infection (for example, lung, prostate) and evidence of positive serology in blood or cerebrospinal fluid [44,45]. This suggests that many cases of cutaneous cryptococcosis are not primary skin lesions at all, but result from fungemia [46,47]. In some cases, this process produces only a single skin lesion.

Examination of the literature shows that there are some patients who meet the criteria for primary cutaneous cryptococcosis [42].

These are generally elderly individuals who do not have any underlying condition known to predispose to cryptococcosis (AIDS, sarcoidosis, T cell lymphoma, or chronic oral steroid therapy). Often, they give a history of local skin injury, sometimes even associated with a peck by a bird that might be carrying *Cryptococcus*. Often, strains isolated from such lesions belong to *Cryptococcus neoformans* serotype D [48]. In AIDS patients, cutaneous cryptococcal infections may also be superimposed on some other process such as Kaposi's sarcoma [49] and are really part of a disseminated infection.

It is important to emphasize that these are observed criteria and have not, by virtue of the rarity of cutaneous cryptococcosis, been subjected to analysis of sufficient scientific rigor. However, the implications for therapy are sufficiently important that it is recommended that patients who meet the broad criteria for primary cutaneous cryptococcosis, after rigorous investigation to exclude disseminated disease, receive treatment with an oral azole antifungal agent, such as fluconazole (at least 200 mg daily) or itraconazole (at least 200 mg daily) until the lesions have resolved, treatment being extended for at least 1 month thereafter. Serology should be monitored again before the end of treatment and for 6 months after the end of treatment. This approach is provided as a guideline based on anecdotal experience and has not been the subject of a clinical trial.

### Key points: systemic mycoses

- Systemic mycoses are not usually treated primarily by dermatologists.
- Most opportunistic mycoses are seen in immunocompromised patients.
- Skin lesions in most endemic mycoses, such as paracoccidioidomycosis, probably result from lung dissemination.
- They occasionally exhibit direct skin invasion following infiltration of organisms, or indirect skin manifestations such as erythema nodosum or multiforme, probably from immune complex deposition.
- Although many patients with cutaneous cryptococcal infection probably develop skin involvement as a result of internal spread, some cases of primary cutaneous cryptococcus do exist.
- Anecdotal evidence suggests that itraconazole or fluconazole might be effective in such cases.
- A number of controlled clinical trials on the treatment of systemic mycoses are currently being conducted by the US Mycosis Study Group, the MRC and the EORTC.

# Streptococcal cellulitis/erysipelas of the lower leg

Vinod E. Nambudiri and Michael Bigby

Department of Dermatology, Harvard Medical School and Beth Israel Deaconess Medical Center, Boston, MA, USA

## Background

### Definitions and etiology

Cellulitis is inflammation due to infection of the superficial and deep dermis. It is characterized by local heat, erythema, induration, or pain in the affected area. Cellulitis can occur in any area, but it occurs most commonly on the lower extremities. Erysipelas is a spreading infection of the superficial dermis. In practice, these may coexist. Use of the term “erysipelas” to describe spreading mid-facial streptococcal infection is universal, but the same infection in the lower leg may be termed cellulitis (in the UK and USA) or erysipelas (in Europe).

Cellulitis occurs in many situations and due to many organisms. In most studies from dermatology departments, the lower leg is the main site of involvement (75% to over 90%), and most cases are streptococcal. Even amongst unselected or emergency department patients, the lower leg usually accounts for about two-thirds of cases. Proving streptococcal etiology is difficult. Staphylococcal infection is the most important differential diagnosis at this site.

This chapter focuses on cellulitis of the lower leg (Figure 46.1), and on the clinically important questions on its management.

### Clinical features

Typically, streptococcal cellulitis is initially manifest as swelling of the forefoot, accompanied or preceded by general malaise and/or fever [1–4]. It progresses as proximally spreading, confluent, tender erythematous swelling accompanied by malaise, fever, and often rigors. Swelling and pain may be severe; blistering, lymphangitis, and/or lymphadenopathy may occur. Although it is often used as a diagnostic criterion, significant pyrexia may be absent in more than half of patients admitted to hospital [5,6].

### Incidence/prevalence

No accurate data are available. The incidence is overestimated if other infections are classified as cellulitis, or underestimated if cellulitis treated in the community is not included. Abscesses or localized wound infections, and/or cellulitis at other body sites, are often included in incidence/prevalence data.

Cellulitis and abscesses accounted for 158 consultations per 100 000 person-years at risk in the UK in 1991, and skin and subcutaneous infections resulted in 29 820 hospital admissions that year [7], but these data are not specific to cellulitis of a pattern relevant to this chapter. In a UK district general hospital, about 3% of admissions were for cellulitis [8]. Incidence data from UK hospitals reveal 69 576 episodes of cellulitis and 516 episodes of erysipelas in 2004–2005 [8].

### Importance and prognosis

In those with severe symptoms such as high fever, blistering, severe pain, or lymphadenitis, or in whom systemic features resolve with antibiotics but redness and swelling persist, hospital admission is usually recommended. In those who do require admission, numerous studies [4,9,10] and UK National Health Service data (cited in Pearse *et al.* [7]) document a mean duration of stay of 9–10 days. Recent data from the UK National Health Episode Statistics show a trend toward shorter mean durations of 5–6 days, representing a significant decrease in health-care costs [11]. Uncommonly, cellulitis may progress to sepsis, necrotizing fasciitis, or streptococcal toxic shock syndrome, each of which has significant mortality.

In addition, long-term sequelae such as persistent edema, leg ulceration, or further episodes are all common (see the section on long-term complications below). Morbidity is therefore significant.

### Diagnostic tests

The diagnosis of cellulitis is largely based on clinical features of localized swelling and erythema of the skin, accompanied or preceded by general malaise or fever. Streptococci may be identifiable by culture of swabs from macerated toe webs, blister fluid, or ulceration (but leg ulcers, if preceding cellulitis, may be colonized with numerous bacterial species). Aspiration or skin biopsy may yield positive cultures; streptococcal antigen identification by direct immunofluorescence of skin biopsies or using latex agglutination increases the diagnostic rate but is not routinely performed.

Analysis of the results of cultures in six studies (including 284 patients) documented a causative organism in 29% of cases [3]. One

**Figure 46.1** Streptococcal cellulitis of the leg: marked erythema, edema, and early blistering.

study (229 patients, 79% with leg cellulitis) using cultures and antistreptolysin-O titers (ASOTs), isolated group A streptococci from a relevant skin site in 19%; ASOT was elevated acutely in 30%, but more commonly (61%) in convalescent sera [12]. If a relevant organism is identified in the ascending lower leg pattern of cellulitis, streptococci of group A (less frequently group G) account for about 80% of isolates. One review of 808 patients with cellulitis of intact skin (of any body site) with positive needle aspiration or punch biopsy skin cultures demonstrated a causative organism in 16% of cases, with *Staphylococcus aureus* as the most common etiologic agent (accounting for 50% of positive cultures), drawing attention to the need for heightened clinician awareness of local epidemiologic patterns of incidence and resistance in community-acquired bacterial infections of the skin [13].

The growing prevalence of methicillin-resistant *Staphylococcus aureus* (MRSA) is also manifested by an increasing frequency of this organism as a common cause of cellulitis. Of 384 patients with community-acquired staphylococcal skin or soft tissue infections seen in a large urban hospital in the USA, 72% were caused by MRSA [14].

### Aims of treatment

- To resolve symptoms, reduce the duration of hospital admission, and avoid or reduce sequelae such as edema.
- To prevent subsequent episodes.

### Outcome measures

- Resolution of fever/malaise, erythema, edema (or halting progression of erythema; see the discussion below). The “NICE CKS” guidelines – a series of evidence-based clinical knowledge summaries developed by the UK National Institute for Health and Clinical Excellence for the care of patients in primary care settings – cite cure at 14 days as a suitable outcome measure [15].
- Elimination of risk factors, especially tinea pedis if relevant as a portal of entry.

### Methods of search

A search was carried out using “cellulitis” or “erysipelas” in the Cochrane Database of Systematic Reviews, Medline, and Embase databases up to May 2007. A search for new updates to the literature was performed in November 2012.

Key case series and interventional studies were identified from references obtained and from the authors’ files. A Cochrane review on the subject of interventions for cellulitis and erysipelas was published in 2010.

## Questions

### What are the factors that predispose to lower-leg cellulitis?

#### Evidence summary

The clinical diagnosis of cellulitis relies on recognition of localized swelling and erythema that, in the appropriate clinical context, suggest a bacterial infection. When patients clinically diagnosed with cellulitis are compared with matched control subjects, several factors have been identified associated with an increased risk of cellulitis. Lower-leg lymphedema and venous insufficiency have been identified as predisposing factors associated with the development of lower-leg cellulitis. The presence of disrupted skin integrity, compromising the barrier function of the skin and thus providing a portal of entry for microbial species, is also consistently linked with patients with cellulitis more frequently than control subjects. The presence of interdigital toe web-space infection such as tinea pedis has been variably identified as a risk factor, likely also due to associated barrier dysfunction. Obesity – with or without the presence of lower-extremity edema – and diabetes mellitus have also been identified in selected studies as risk factors for the development of cellulitis.

#### Case-control studies

Patients admitted to the hospital with lower-leg cellulitis ( $n = 167$ ) were compared with controls ( $n = 294$ ; matched for age, sex, and hospital) across seven hospital centers. Lower-leg cellulitis or erysipelas was defined as the sudden onset ( $<24$  h) of a well-demarcated cutaneous inflammation, with fever  $>38^\circ\text{C}$  or chills. Patients under 15 years of age and patients with abscess or necrotizing fasciitis were excluded from analysis. One dermatologist in each study center conducted direct interviews with a structured questionnaire and clinical examination of cases and controls with regard to risk factors for cellulitis. Risk factors were lymphedema, odds ratio (OR) of 71.2 (95% confidence interval [CI], 5.6–908), presence of a portal of entry (toe web intertrigo, ulcer, wound, dermatosis) (OR, 23.8; 95% CI, 10.7–52.5), venous insufficiency (OR, 2.9; 95% CI, 1.0–8.7), leg edema (OR, 2.5; 95% CI, 1.2–5.1), and being overweight (OR, 2.0; 95% CI, 1.1–3.7) [16]. Diabetes (identified as a risk factor in some smaller studies) showed no association with the occurrence of cellulitis. Toe web disease was present in 66%, leg edema in 38%, and lymphedema in 18%.

A total of 100 patients were compared with 200 age-matched and sex-matched control individuals, with an emphasis on toe web disease, and using both questionnaires and clinical examinations [17]. Inclusion criteria for case patients were (1) presence of lower-limb cellulitis and (2) the absence of abscess formation or necrotizing fasciitis. Lower-limb cellulitis was defined as a demarcated cutaneous inflammation of sudden onset of less than 72 h duration that was associated with fever, chills, or leukocytosis. The investigators completed a questionnaire for each patient, examined both lower extremities, and skin and toenail samples were obtained from the affected limb to assess for tinea pedis or bacterial infection. Risk factors for cellulitis were previous cellulitis (OR, 31.04; 95% CI, 4.15–32.2), staphylococci or streptococci in the toe webs (OR, 28.97; 95% CI, 5.47–153.48), leg erosions or ulceration (OR, 11.80;

95% CI, 2.47–56.33), and prior saphenectomy (OR, 8.49; 95% CI, 1.62–44.52). Toe web tinea infection was only associated when toe web bacterial infection was excluded from analysis (OR, 3.86; 95% CI, 1.32–11.27) [17].

In a study of 114 Tunisian patients with erysipelas of the leg compared with 208 controls matched for age, sex, and hospital-of-care, direct physician-led interviews and physical examinations were performed to assess risk factors [18]. No laboratory investigations were performed. Significant risk factors identified via multivariate analysis included cutaneous barrier disruption of the lower extremity (OR, 13.6; 95% CI, 6.3–31.0) and the presence of leg edema (OR, 7.0; 95% CI, 1.3–38). None of the general risk factors – being overweight, smoking, sedentary work, alcohol consumption, or diabetes mellitus – were associated with increased risk of lower-extremity erysipelas [18].

### Retrospective studies

Patients with recurrent cellulitis were compared with a group with single episodes (total  $n = 574$ , 81% of which involved the leg, with a retrospective single-institution analysis). Risk factors for recurrence (all statistically significant) were being overweight, venous insufficiency, lymphedema, tinea pedis, and previous regional surgery or trauma [19].

In a case-note review with questionnaire follow-up at up to 3 years after admission, it was found that, of 171 patients, 47% had a history of recurrent episodes and 46% had chronic edema. These two sequelae were strongly associated ( $P = 0.0002$ ) [20]. Chronic edema specific to, or greater in, the post-cellulitis lower leg was identified by 37%. Thirteen percent of the patients had leg ulceration attributed to cellulitis.

In a study of 243 patients and 467 control individuals (matched for age  $\pm 5$  years, sex, hospital, and timing of admission), mycologically proven foot dermatomycoses of various types were found to be the major risk factor for bacterial cellulitis (overall OR, 2.4; interdigital tinea OR, 3.2). Other associations with cellulitis were other portals of entry, a history of previous cellulitis, chronic venous insufficiency, and leg edema [21].

In 647 patients with cellulitis/erysipelas (91.2% in the leg), general or local risk factors were found in 26% (interestingly, only 3.3% had leg edema). Seventy-seven percent of the patients had portals of entry, 50% of which were (predominantly toe web) fungal infections [10]. In a study of 30 patients with lower extremity cellulitis, 13 out of 15 patients (87%) assessed by lymphoscintigraphy had evidence of abnormal lymphatic circulation in the involved lower extremities, with eight of the 15 (53%) demonstrating bilateral lower extremity abnormalities [22].

In 365 patients with cellulitis (76% in the leg), 24% had fungal infections, described as “mostly tinea pedis.” Accurate figures cannot be extracted from the data, but this represents approximately one-third of those with leg cellulitis having tinea pedis [23].

About a quarter of patients with lymphedema will have at least one episode of cellulitis or related skin infection in the affected limb(s), potentially with recurrences every few weeks, and probably with a higher frequency in those in whom the cause is not related to cancer treatment; although cited in a Cochrane review, this is based on unpublished original data. It is not clear that all such inflammatory episodes are truly infective [24].

### Comments

The publications documenting risk factors for lower leg cellulitis probably represent the strongest evidence in this chapter, with con-

sistent results implicating chronic edema (venous or lymphedema), toe web bacterial and/or fungal infection, and obesity as major risk factors. The importance of distinguishing lymphatic from venous edema may be artificial; the two are typically combined once chronic [25], leading to the use of the term “lymphovenous edema.” As a risk factor for cellulitis, it is not clear whether it is the chronicity or severity of edema, or both, that is important. It is important to be aware that cellulitis is not only a consequence of edema, but that it also causes chronic edema, so that there is a vicious cycle leading to further episodes [20,26]. The effect of therapy to address these risk factors needs to be assessed.

Other predisposing factors for cellulitis include intravenous (IV) drug abuse and conditions in which blood vascular anomalies are associated with lymphatic abnormality (e.g., Klippel-Trénaunay syndrome).

## What is the best antibiotic treatment regimen?

### Evidence summary

Antibiotic treatments for cellulitis remain a focus of ongoing clinical research and evidence-based review. A recently completed Cochrane review of treatments for cellulitis and erysipelas provides the most comprehensive assessment to date of therapeutic interventions [27]. The Cochrane review included 25 studies covering 2488 patients with cellulitis. The heterogeneity of study designs and treatment variables (no two studies compared the same two antibiotic treatment regimens) limited the ability to make definitive recommendations following review of the data. The writing group was unable to define the best treatment for cellulitis. However, the reviewers concluded that the limited evidence of three trials [28–30] suggested macrolide and streptogramin antibiotics are slightly better than penicillins for reducing symptoms at the end of antibiotic treatment for cellulitis.

Pertinent clinical questions regarding antibiotic treatment regimens include the specific therapeutic agent, the mode of administration, and the duration of treatment. Previous evidence-based reviews have found no satisfactory randomized studies of antibiotics versus placebo or of IV antibiotics versus the same agent given orally [8], although one such study exists for IV versus intramuscular (IM) administration of penicillin [31]. There are some published summaries of head-to-head comparisons. Most show no difference between the active agents compared [4,32].

The following studies have been chosen as they address specific pertinent issues. Antibiotics used in home treatment programs are discussed later.

### Prospective studies

One randomized controlled trial (RCT) of 81 patients with lower-leg cellulitis compared flucloxacillin alone versus flucloxacillin in combination with benzylpenicillin. This study showed no difference between the two regimens with regard to the number of doses required (mean number of doses, 8.71 for flucloxacillin alone and 8.47 for the dual regimen; mean difference,  $-0.24$  doses; 95% CI for the difference,  $-2.38$  to  $-2.01$ ;  $P = 0.83$ ), next-day temperature (mean difference,  $-0.07^\circ\text{C}$ ; 95% CI,  $-0.76$  to  $-0.62$ ;  $P = 0.84$ ), or area of erythema decrease (mean difference,  $-34\text{ mm}$ ; 95% CI,  $-99$  to  $-31$ ;  $P = 0.30$ ). Pain scores and patients' subjective improvement scores were also similar in the two groups. Overall, this study did not support the addition of benzylpenicillin to flucloxacillin [33].

Another RCT investigating IV benzylpenicillin 4 MU six times daily ( $n = 55$ ) in comparison with IM penicillins (a mixture of benzyl penicillin and procaine penicillin) 2 MU twice daily ( $n = 57$ )

assessed cure rates and local complication rates in the two groups. Recovery was defined by a score of zero for erythema, edema, and pain and by a normal temperature on the 10th day of treatment or before. Patients who showed local or general state complication during the 10 days of treatment or who did not have clinical improvement at the 10th day of treatment were considered treatment failures and left the trial. The investigators found no difference in the cure rate (failure rate 14% IM, 20% IV; absolute risk difference 6%,  $P = 0.40$ ) or local complications (9.1% IV, 7% IM;  $P = 0.477$ ), but 26% had venous inflammation in the IV group [31]. The IV and IM routes were thus equally effective, but there was less treatment-related morbidity with IM penicillin.

A third RCT screened 169 patients with cellulitis, 48 of whom were excluded (exclusion criteria included neutropenia, abscess formation, deep infection, incorrect diagnosis, confined to area of a bite, diabetic foot infections, others). All 121 participants received 5 days of levofloxacin 500 mg/day and were then assessed; 87 were randomly assigned to either a further 5 days of treatment ( $n = 43$ ) or 5 days of placebo ( $n = 44$ ). Participants were excluded from day 5 randomization if they had worsening cellulitis, no improvement, positive blood culture, ulceration, an alternative diagnosis (e.g., bursitis), abscess, or another nidus of infection. Both groups achieved 98% success (clearance by 14 days, no relapse within 28 days) [34].

A parallel-group open trial of 289 patients with erysipelas (cellulitis) compared oral pristinamycin versus IV and then oral penicillin; 102 patients in each limb were able to be assessed for the primary end point (cure rate at 24–25 days). Exclusions were mainly for protocol violations (additional therapy, missed therapy, missing data). Both drugs have a high level of antistreptococcal activity. The cure rates (per protocol and intention to treat) were 81% and 65% for pristinamycin in comparison with 67% and 53% for penicillin, both statistically significant differences (per-protocol absolute risk difference, 14%; 97.06% CI, 3.3% to  $\infty$ ; intention-to-treat absolute risk difference, 12%; 97.06% CI, 1.7% to  $\infty$ ) [28]. Adverse effects included a higher frequency of (usually nonlimiting) gastrointestinal symptoms with pristinamycin.

Recent attention has focused on treatment of cellulitis with regimens providing adequate coverage for MRSA in light of the organism's increasing prevalence. A randomized, evaluator-blinded, multicenter trial of 103 patients with cellulitis or erysipelas requiring hospitalization compared treatment with IV daptomycin versus IV vancomycin; mean treatment durations were 6.1 days and 6.2 days, respectively. 32.0% of daptomycin- and 35.3% of vancomycin-treated patients in the study reported a previous episode of cellulitis or erysipelas within the prior 5 years. The clinical success rate for complete clearance or improvement, judged 7–14 days after the final dose of antibiotic, was comparable for both treatments, at 94.0% for daptomycin versus 90.2% for vancomycin [35].

### Retrospective studies

In 365 patients (76% lower leg site), penicillin alone was used in 45%. Other antibiotics were significantly more frequently used in those with predisposing conditions or in those who were hospitalized. (Patients with bullous cellulitis or with streptococcal toxic shock syndrome were excluded.) The authors documented a median hospital stay of 5 days in the "penicillin alone" and the "other antibiotics" groups, but a longer maximum stay in the "other antibiotic" group (28 vs 20 days) and an overall statistically different mean duration of stay [23]. The "other antibiotic" group also had a higher rate of predisposing conditions. The authors concluded that there is no advantage with the use of antibiotics other than penicillin.

### Comments

The most comprehensive review of the evidence to date on the topic of treatment for cellulitis (the Cochrane review completed in 2010) provides insight into the challenge of determining the therapeutic regimen for management of this condition [27]. The reviewers were not able to identify the best treatment for cellulitis based on the review of the current literature.

While macrolide and streptogramin antibiotics may provide better efficacy than penicillin antibiotics for symptom reduction, several studies have validated the role of penicillins as a treatment of streptococcal cellulitis. Benzylpenicillin or phenoxymethylpenicillin have a very low minimal inhibitory concentration (MIC) against streptococci, excellent response rates in most streptococcal disease, and a very low and unchanging (over many decades) risk of streptococcal resistance [36–38]. The main reservations about the use of penicillin alone are cases of nonstreptococcal etiology.

Flucloxacillin alone has been recommended as first-line therapy for cellulitis by guidelines such as those of the Clinical Resource Efficiency Support Team (CREST) [39] and NICE CKS [15]. The Infectious Diseases Society of America recommends penicillin for erysipelas (well-demarcated tender plaque) and a penicillinase-resistant penicillin or first-generation cephalosporin for cellulitis, although they also state that most cellulitis is streptococcal (staphylococcal infection being rare unless associated with an underlying abscess or penetrating trauma) [40].

The increasing prevalence of MRSA, especially as a cause of abscesses and other cutaneous infections, has led to the statement that the evidence used in creating current guidelines for the treatment of skin and skin structure infections has significant limitations, especially as many studies have used comparative noninferiority protocols [41]. Further systematic review of therapeutic interventions for the treatment of MRSA cellulitis and skin infection is warranted for this increasing public health challenge.

### Where should patients be treated?

#### Evidence summary

Most studies of cellulitis have been conducted in secondary care facilities. The number of patients previously treated in primary care is unclear. The possibility of making a definitive choice for treatment at home has been assessed recently as another locus of clinical care delivery. Randomized trials allocating patients to either home or inpatient care contain several methodological constraints regarding patient selection. Several innovative models of home therapy are currently being explored. The very limited rigorously designed studies on this topic suggest that home treatment for cellulitis may have the potential to yield similar clinical outcomes for a selected population of patients.

#### Prospective studies

One RCT was undertaken in patients perceived to have cellulitis requiring IV antibiotics and with no contraindication to home therapy (home,  $n = 98$ ; hospital,  $n = 96$ ) [42]. There were no significant differences in the time to the primary end point, cessation of advancement of erythema (mean, 1.50 days with home treatment and 1.49 days in the hospital group; mean difference,  $-0.01$  days; 95% CI for the difference,  $-0.3$  to  $-0.28$ ), or in the days on IV antibiotics (cephazolin at home; various others also used in hospital), days on oral antibiotics, overall days of treatment, complications, pain, or function; home treatment was preferred. However, there were several exclusion criteria, including previous cellulitis at the same site within 1 month, neutropenia or neutrophilia, signs of

sepsis, comorbidities (“severe” diabetes, obesity, peripheral vascular disease, alcoholism, immunosuppression), directly cellulitis-associated factors (such as blistering, tissue necrosis, severe lymphangitis, or a large area of cellulitis), or refusal to enter the trial. In order to randomly assign 200 patients (into groups of 101 and 99, with 10 rediagnosed after randomization), 658 patients fulfilling the entry criteria had to be screened (thus, only 30% of the potential patients actually entered the trial).

### Retrospective studies

A total of 266 episodes of cellulitis treated in a hospital-initiated “hospital-in-the-home” program were reviewed. After accounting for some miscoding (six episodes of ongoing cellulitis, 18 cases of pilonidal sinus), the length of stay was similar in the home and hospital groups (mean, 7.3 days at home and 7.1 days in hospital) [43].

In a review of 124 patients with cellulitis who were considered suitable for home IV therapy in accordance with local “hospital-in-the-home” guidelines [44], the exclusion criteria included children, bites, deep involvement or surgical review necessary, signs of severe systemic illness, leukopenia, or white cell count  $>20 \times 10^9/L$ . Two-thirds of the patients had cellulitis of the leg; over 99% were treated with cephazolin 2 g twice daily. Eighty-five percent were treated successfully with a mean IV antibiotic duration of 6.24 days. The published details are insufficient for separate analysis of the lower-leg subset.

A study compared 112 patients with “uncomplicated cellulitis” and 230 retrospective control individuals to determine the benefits of a protocol for baseline suitability for treatment at home, with recording of symptoms and signs by nurses and criteria for medical review [45]. Most home treatment was initially once-daily IV ceftriaxone, then 7 days of oral clindamycin or flucloxacillin. Using a protocol led to a reduction in the median duration of IV antibiotic therapy (3 days, vs 4 days in the pre-protocol controls), and reduced physician review (19% vs 100%), but the outcomes, complications, and readmissions were similar. Exclusions, which were also applied to the control group by examination of case records, included severe localized pain, rapid evolution, blistering, hypotension or other features of sepsis, drug or alcohol misuse, some patients with wounds or trauma, and social factors that would make home treatment difficult. The number of exclusions was not stated, but of those entering the home treatment program, 36% had had an immediately preceding hospital admission for their cellulitis (45% in the retrospective controls).

An alternative to home IV antibiotic treatment is early discharge once IV therapy is no longer considered necessary. In a retrospective study, 17% of 374 patients were discharged on the same day as IV antibiotics were stopped, rather than having a further in-patient night for observation [46]. Although only 40 (15%) in this series had cellulitis, none of these had significant pyrexia or local symptom recurrence on the final “observed” or “unobserved” day and none required readmission within 14 days.

A retrospective analysis of 334 episodes of outpatient parenteral antibiotic therapy (OPAT) in the UK included 198 episodes of cellulitis or erysipelas, all but one treated with IV ceftriaxone. Patients received antibiotics either at local infusion centers or self-administered (or administered by a family member or carer) at home. A cure rate of 92% at the end of treatment (mean duration of treatment with IV antibiotics was 7.04 days) was assessed by specialist nurses for the patients with skin infections. The authors calculated 972 inpatient hospital bed-days for skin infections were

saved by OPAT treatment of cellulitis and estimated significant cost savings from care in the outpatient program compared with inpatient hospitalization for the same diagnosis [47].

### Comments

All of these studies suggest that treatment at home is safe and effective, especially if supported by a carefully prepared protocol. However, all need to be interpreted with caution; all of the studies involved decisions about patients’ suitability for home treatment and excluded patients with more severe disease or with factors precluding home therapy. None, therefore, represents an RCT of unselected subjects. In one large retrospective review of 647 patients with cellulitis (91% leg), only 27% were felt to require hospitalization, with a mean duration of stay of 9 days [10]. However, the one prospective study [42] was only able to recruit 30% who fulfilled the criteria for needing IV therapy. The number of screened but excluded subjects is not apparent in all of the above studies, but the available data suggest that a minority of patients who would normally require admission can actually be treated at home.

In addition, some of the end points used have uncertain clinical relevance. “Cessation of advancement of erythema” is an end point that appears appropriate, but some hospital admissions are for patients in whom “erythema is not resolving.” Indeed, this condition – sometimes (probably incorrectly) termed “chronic cellulitis” – is thought by many to represent an ongoing immunological response to infection [34], although, particularly if bilateral, it may just represent background lymphedema. The important point is that it is not an end point that automatically excludes subsequent hospital admission.

Early discharge after IV antibiotics does not appear to be associated with a greater risk of adverse events [46], but there was a bias in that patients who were discharged on the day on which IV antibiotics were stopped were younger and had fewer comorbidities. Home antibiotic treatment may also offer a lower cost of care than inpatient admission, suggesting an opportunity for shared savings in the management of patients with cellulitis.

### What factors are associated with or predict short-term morbidity, severe disease, or mortality, and what tests should be done?

Short-term complications of cellulitis include severe edema, blistering, leg ulceration, abscess formation, unrecognized infection by rare organisms, necrotizing fasciitis, septicemia, streptococcal toxic shock syndrome, and death. Severe complications are, however, rare. Clinical features that suggest necrotizing fasciitis are discussed elsewhere [1,48–50]; laboratory tests that may be useful in this diagnosis or that of streptococcal toxic shock syndrome (the two are commonly associated) are presented as they are pertinent to the question of “what tests should be done?”

Abbreviated criteria for streptococcal toxic shock syndrome (see Bisno and Stevens [1] for more detailed criteria and a definition of “definite” or “probable” case) include:

- 1 Isolation of group A streptococci.
- 2 Signs of severity:
  - i hypotension (systolic blood pressure  $<90$  mmHg);
  - ii two or more of:
    - renal impairment (creatinine  $>177 \mu\text{mol/L}$ ) or  $>2\times$  upper limit of normal for age;
    - coagulopathy (platelets  $<100 \times 10^9/L$  or evidence of disseminated intravascular coagulation);

- liver involvement – transaminases or bilirubin  $>2\times$  upper limit of normal for age;
- adult respiratory distress syndrome/capillary leak syndrome;
- generalized macular rash;
- soft-tissue necrosis (includes necrotizing fasciitis, myonecrosis, gangrene).

A clinical suspicion of necrotizing fasciitis (especially “crescendo” pain, tender induration, pallor, or cyanosis superimposed on erythema, crepitus, lack of lymphangitis, hypoesthesia, foul exudates, muscle pain or weakness, and increasing systemic symptoms – e.g., fever, confusion, hypotension) should prompt consideration of laboratory evaluation of renal function, coagulation factors, and liver involvement, as well as surgical assessment. Bullae may occur in either “ordinary” cellulitis or in more severe infection; severe pain often precedes skin signs in necrotizing fasciitis [50], and bullae, when they appear, are often on a background of vague dusky discoloration rather than of acute erythema [48].

### Evidence summary

A systematic review of blood cultures in patients with cellulitis reveals that they are infrequently positive, with a causative organism identified in fewer than 10% of cases. When organisms are present, however, tailored antibiotic therapy may be achievable. Retrospective data reveal a low likelihood of death from cellulitis. No single diagnostic test appears superior for predicting prognosis of patients with cellulitis, but elevated markers of systemic inflammation suggest an increased risk of adverse outcomes.

### Systematic review

A review of 17 retrospective studies or case series of nonfacial cellulitis [51] found that blood cultures were usually negative, and if positive did not alter the empirical therapy already commenced. On the basis of the studies reviewed, the frequency of positive blood cultures in uncomplicated cellulitis is about 2–5%. A recently completed systematic review of 28 studies with reported blood culture data in 2185 patients with cellulitis or erysipelas found 4.6% of 607 patients with erysipelas and 7.9% of 1578 patients with cellulitis had positive culture results [52]. In these patients with erysipelas with positive blood cultures, 46% were *Streptococcus pyogenes*, 29% were other  $\beta$ -hemolytic streptococci, 14% were *Staphylococcus aureus*, and 11% were Gram-negative organisms. For cellulitis, 19% of positive cultures grew *Streptococcus pyogenes*, 38% were other  $\beta$ -hemolytic streptococci, 14% were *Staphylococcus aureus*, and 28% were Gram-negative organisms [52].

### Prospective studies

We found no prospective studies.

### Retrospective studies

In one study [23], there were no deaths amongst 365 patients, although those with bullous cellulitis were excluded, as were an unspecified number with streptococcal toxic shock syndrome (a condition with a mortality rate of 50%).

In a single-institution analysis of risk factors for poor outcome in 332 adults with cellulitis [53], the body sites were not stated, but localized cellulitis of the orbit and infections related to surgical wounds, diabetic foot ulcers, or IV drug use were excluded. Death occurred in 16 (5%) within 1 month (including eight, 2%, within 72h), and was statistically associated with male sex, congestive

cardiac failure, morbid obesity, any two comorbid conditions (diabetes, cancer, cirrhosis, congestive cardiac failure, chronic obstructive pulmonary disease, morbid obesity, or HIV infection), shock, hypoalbuminemia, elevated creatinine ( $>150\mu\text{mol/L}$ ), and *Pseudomonas* infection (which accounted for five of the 16 deaths).

In the same study [53], complications in 103 patients (31%) included a need for surgical debridement or other surgery (29%), shock (4.5%), or other systemic complications (11.5%). Although not significantly associated with death, an absence of necrosis at presentation was significantly linked with early discharge without complications.

In a review of 647 cases, 91% affecting the leg, only one patient developed necrotizing fasciitis (although only 176 of the patients in this series were felt to have sufficient severity of disease that admission was necessary) [10].

In a series of 229 patients (79% with a leg site), 14% had local skin necrosis or abscess, but none developed streptococcal toxic shock syndrome [12].

In 200 patients with soft-tissue infection (66% affecting the leg), the mean C-reactive protein and erythrocyte sedimentation rate at admission were significantly higher in the group requiring more than 10 days’ admission in comparison with those discharged earlier [54].

A retrospective analysis of 395 episodes of cellulitis or erysipelas (74% affecting the lower leg) requiring hospitalization at a single institution over an 8-year period was reported in 2010 [55]. Patients with local complications, such as abscess or bursitis at presentation, were excluded, as were those with deep infection or a diagnosis of necrotizing fasciitis. The analysis found an overall mortality of 2.5% and the development of systemic or local complications in an additional 28.4% of patients. Multivariate analyses identified preexisting congestive cardiac failure, neutrophilia/penia within 24h of admission, albumin  $<30\text{g/L}$ , purulent discharge from the cellulitic area, altered mental status, and the presence of bacteremia as factors associated with an increased odds of adverse outcomes (local or systemic complications or death). A five-point scoring system was constructed by the study’s authors to stratify patients at high risk of adverse outcomes on presentation based on 198 randomly selected patients and was validated using the other 197 in the study; the scoring system assigns five points for altered mental status, and two points each for congestive cardiac failure, discharge from cellulitis site, hypoalbuminemia, and neutrophilia/penia, with scores below 4 having a low risk of adverse outcomes. Hospital stays longer than 7 days were necessary in 35.1% of patients. Factors associated with an increased odds of long hospitalization included age over 60, albumin  $<30\text{g/L}$ , symptoms for more than 4 days, bacteremia, and MRSA identified as the causative agent [55].

Data regarding the incidence of superficial and deep venous thromboses in cellulitis or erysipelas of the lower extremities reveal they are relatively infrequent complications. The incidence across studies in which a systematic investigation for deep venous thrombosis was performed (eight studies involving 990 patients) using Doppler ultrasonography, venography, or fibrinogen-uptake test was calculated as 2.7% (95% CI, 1.71–3.73%) [56].

In a retrospective study of 43 cases of necrotizing fasciitis [57], streptococcal necrotizing fasciitis was more likely to affect previously healthy individuals, was only initially suspected in 12%, and had a higher mortality than nonstreptococcal causes. Mean serum creatine phosphokinase (CPK) levels were much higher in patients with necrotizing fasciitis than in those with cellulitis, presumably

reflecting the deeper involvement of musculature, and may be a useful clinical indicator of severity.

The details of 89 patients with necrotizing fasciitis and 225 control individuals (with severe cellulitis or abscess) were used to develop a laboratory risk indicator for necrotizing fasciitis score, which was then validated on a cohort of 140 patients [58]. Predictive laboratory tests proved to be elevated C-reactive protein ( $>150$  mg/L), leukocytosis (especially  $>25 \times 10^9$ /L), low hemoglobin (especially  $<11$  g/dL), hyponatremia  $<135$  mmol/L, creatinine  $>141$   $\mu$ mol/L, and glucose  $>10$  mmol/L; a scoring system of 0–13 was derived, which has positive and negative predictive values of 92% and 96%, respectively, at a cut-off score of 6.

### Comments

Deaths and severe complications are rare among patients with cellulitis. Causes of death are mainly septic shock, multi-organ failure, or related to underlying disease.

There are several factors that contribute to the duration of admission. The duration of admission and the duration of antibiotic therapy are often used as end points of cellulitis treatment. They probably reflect costs, but are not necessarily an accurate surrogate for severity (social issues may contribute to prolonged admissions).

Very few acutely admitted patients will fail to have a full blood count and basic electrolytes tested. Test results such as elevated CPK, rising creatinine, rising liver transaminases, or neutrophilia, may all be associated with severity or with development of streptococcal toxic shock syndrome and/or necrotizing fasciitis. Bacteremia is uncommon in uncomplicated cellulitis, but occurs in about half of patients with necrotizing fasciitis. It appears reasonable to reserve this test for those with recognized local or systemic severity factors. If standard bacteriology cultures are negative, the streptococcal *speB* gene may be detectable in tissue samples using polymerase chain reaction techniques. If present, infection with MRSA appears to predict poor prognosis for patients with cellulitis, and treatment should proceed accordingly for coverage of MRSA.

## What are the long-term complications?

### Evidence summary

Long-term consequences of cellulitis are particularly seen in patients with more severe episodes of infection. Long-term complications include chronic edema of the lower extremity, which has also been identified as a risk factor for the development of cellulitis (reviewed above). A subset of individuals is affected by recurrent cellulitis, often in the same extremity as previously affected. There appears to be a correlation between chronic edema and recurrent cellulitis, representing a vicious cycle of repeated infection and lymphatic distention.

### Prospective studies

We found no prospective studies.

### Retrospective studies

Recurrent episodes were observed in 48 (21%) of 229 patients (79% of cases affected the leg) [12]; 27 of the 229 (12%) had a history of one previous episode, 36 (16%) had had more than one previous episode, and half of those with subsequent episodes had more than one recurrence (most commonly, although not statistically significantly, in those with an underlying cause).

Recurrent episodes were observed in 29% of 143 patients [59]; 13% had two or more further episodes. Risk factors were documented in 26% of those with single episodes, in comparison with 76% of those with recurrent episodes, although only venous insufficiency was statistically significant.

In 70 patients (all with lower-leg sites), morbidity included persistent edema (9%), leg ulceration (3%), and previous or further episodes (28%) [6].

Of 167 admissions (all with lower-leg sites), 77% were for a first-ever episode and 23% for a recurrent episode [16].

Among 459 patients with leg cellulitis (81% of a series of 574 patients), fewer than 30% were admitted due to a first episode of cellulitis; most (about 37% of leg cellulitis admissions during the study period) were for a second episode at the same site, and one-third were due to a recurrent episode at a different site (not stated, but probably the other leg, as the main risk factors in this study affected the legs) [19].

Among 171 patients (retrospective review with questionnaire follow-up at up to 3 years after admission), 47% had a history of recurrent episodes and 46% had chronic edema. There was a strong association between these two factors ( $P = 0.0002$ ) [20]. Chronic edema specific to, or greater in, the previously affected leg was identified by 37%, and 13% had leg ulceration attributed to cellulitis. Both of these complications were less frequent in patients treated with longer courses ( $>28$  days) of penicillin, but the difference did not reach statistical significance. Half of the recurrent episodes of cellulitis had not required hospital admission.

A UK Dermatology Clinical Trials Network (UKDCTN) pilot study to evaluate possible recruitment into trials of cellulitis showed a similar potential for underestimation of recurrent episodes: 40% of patients with cellulitis described previous episodes (multiple in 54% of these), but only 55% had been admitted to hospital during their most recent previous episode [60].

In 209 episodes of leg cellulitis, 35 patients (16.7%) had recurrences within 2 years [61]; possible predictive factors for recurrence were evaluated, and tibial area involvement, prior malignancy, and dermatitis of the ipsilateral limb were all independent risk factors for recurrence on multivariate analysis, with hazard ratios (HRs) of 5.02, 3.87, and 2.9, respectively. If all three were present, the estimated probability of recurrence was 92.8% (95% CI, 51.9–98.9%). Additional factors that had univariate significance included lower-leg edema or venous insufficiency (HR, 3.52 and 3.88, respectively). Interesting factors that did not have even univariate significance included tinea pedis (HR, 1.31) and ipsilateral deep venous thrombosis (HR, 1.66).

A review of 237 patients with lymphedema and recurrent cellulitis demonstrated a direct correlation between the severity of lymphedema and the frequency of recurrence [26].

In a review of 26 patients with lymphatic disorders, decreased lymphatic flow was found to be related to the time since a venous thrombosis, the occurrence and number of episodes of cellulitis/lymphangitis, and use of the saphenous vein for arterial surgery [62].

### Comments

The main long-term complications are persistent edema, a high risk of further episodes, and a less prominent increase in risk of leg ulceration. In addition, there appears to be a significant link between edema and recurrent cellulitis, which is expected, since edema is a well-documented risk factor. A vicious cycle of infection and lymphatic damage may thus be encountered [17,20,62,63].

Any cause of chronic edema, or ongoing portal of entry for streptococci, will predispose to recurrence. It is uncertain why previous malignancy predisposes to recurrences [61]. Lymphatic obstruction caused by tumors is a plausible explanation [24]. It is also uncertain why involvement of the tibial area is linked with a risk of recurrence [61], although involvement of the tibia may have been a surrogate for severity, as the reference comparator was involvement of the foot.

## Does prophylaxis work, and in which patients?

### Evidence summary

No systematic reviews of interventions for prophylaxis of cellulitis have been completed. Randomized controlled trial data available to date point to a protective effect of prophylactic antibiotics. Questions for further investigation remain as to the indications and duration of such therapy. Limited data are available for other prophylactic strategies.

### Antibiotics

#### Prospective studies

An RCT of patients with venous or lymphatic edema who had suffered two or more episodes of cellulitis in the preceding 3 years documented two recurrences in an interventional group of 20 patients treated with prophylactic penicillin ( $n = 15$ ) or erythromycin for penicillin-allergic patients ( $n = 5$ ) in comparison with eight recurrences in 20 control individuals ( $P = 0.06$ ) over a median period of follow-up of 15 months [64].

An RCT of patients with two or more episodes of cellulitis (mainly in the leg) found no recurrences in 16 patients treated with erythromycin, in comparison with 16 control individuals, in whom there were nine recurrences in eight (50%) patients (40 patients entered) [65].

An RCT in patients with recurrent leg cellulitis used IM benzathine penicillin in 24 patients (18 evaluable) in comparison with 34 control individuals (26 evaluable). The active group had no recurrences within a mean of 11.6 months of follow-up, compared with nine (35%) of the controls [66].

In the largest double-blind, randomized, controlled study to date of prophylaxis to prevent further episodes of cellulitis, 123 individuals who had had one or more episodes of cellulitis were randomized to 6 months of low-dose oral prophylactic penicillin V (250 mg twice daily) or placebo twice daily and followed for up to an additional 30 months thereafter (PATCH II) [67]. Patients were excluded from the trial if they had taken antibiotic prophylaxis for the prevention of cellulitis in the preceding 6 months before enrolling. Initial trial design called for the recruitment of 400 study participants, but given difficulties in achieving target recruitment rate, the study was closed after 2 years of recruitment [68]. While not reaching statistical significance, prophylactic treatment with penicillin did show a 47% reduced risk of recurrent cellulitis (HR, 0.53; 95% CI, 0.26–1.07,  $P = 0.08$ ) without differences in adverse events [67].

A second, large randomized trial of cellulitis prophylaxis assessing 12 months of prophylactic penicillin V in patients with at least two previous episodes of recurrent cellulitis (PATCH I) published its findings in May 2013 [70]. Two hundred and seventy-four patients with two or more episodes of cellulitis were randomized to receive either penicillin (250 mg twice daily) or placebo for 12 months, with the primary outcome of interest a first recurrence of cellulitis. During the 1 year of prophylaxis, participants receiving penicillin had a significantly lower recurrence rate (22%) compared

with those receiving placebo (37%; HR, 0.55). However, there was no statistically significant difference between the two groups in the 2 years following the 12-month study period, with similar rates of cellulitis recurrence in the two groups (both 27%) over the next 2 years, suggesting a protective effect limited to periods of active antibiotic prophylaxis.

### Tinea pedis and toe web intertrigo

Tinea pedis or toe web maceration are well-reported risk factors as a portal of entry for infection causing cellulitis [16,21] and have thus been suggested as possible targets for prophylaxis, with some support from individual cases or small groups of cases. However, some larger studies cast some doubt on whether prophylactically treating web space infection is likely to prevent recurrent cellulitis.

In a study primarily investigating the link between edema and recurrent episodes, toe web disease was not well documented by admitting physicians and was only recognized by 15% of patients in a follow-up survey [20]. This prevalence compares with a prevalence of 66% in 167 patients with cellulitis who were examined by dermatologists [16]. Tinea pedis did not have significance as a risk factor for recurrence in a predictive model based on 209 episodes with 35 recurrences [61]. In a study of antibiotic prophylaxis discussed above [65], the 50% recurrence rate in the control group occurred despite treatments for tinea pedis.

### Control of lymphedema

We found no trials.

### Comments

The studies of oral antibiotic prophylaxis suggest that it is beneficial. In a retrospective study of 143 patients in which 19 (13%) had multiple episodes over the following 3 years, prophylaxis was viewed as possibly cost-effective in those with predisposing factors and severe attacks [59].

Despite limited evidence, prophylaxis is used relatively widely. Pavlotsky *et al.* discussed the use of long-term (usually permanent) penicillin in their patients with either recurrent or high-risk primary episodes, and mentioned that 8% of their patients with a recurrence had this whilst on prophylaxis [19]. However, they did not put this into the context of numbers of patients receiving prophylaxis or recurrences after stopping prophylaxis. Among 68 dermatologists who had an interest in research into prophylaxis for cellulitis, 31 used long-term (>1 year) low-dose penicillin for patients with recurrent episodes, and 22 did so if there was a significant risk factor such as lymphedema (UKDCTN, unpublished). The lack of streptococcal resistance to penicillin over many decades [36–38] and its safe use in post-splenectomy patients suggest that this approach is safe for prophylaxis. The CREST guideline suggests that prophylaxis “may be worth trying” in patients who have had two or more episodes of cellulitis at the same site [39]; however, there are reservations about the strength of evidence, which antibiotic and route of administration is best, whether patient-initiated treatment may be more effective than long-term prophylaxis, and whether a prolonged course of treatment after an episode may prevent recurrences.

As documented above, the evidence for prophylaxis of tinea pedis or edema is lacking, albeit logical.

A wider discussion of prophylaxis is provided by Becq-Giraudon [69].

## Key points

- A Cochrane review of interventions for cellulitis completed in 2010 was not able to define the best treatment. This remains an area of ongoing randomized clinical trial study.
- In a normal immunocompetent person, without skin breaks, wounds, or abscess formation, only a few pathogens (usually streptococci or staphylococci) cause cellulitis or other skin or subcutaneous infection [2,40]. Initial therapy should concentrate on these two organisms.
- Community-acquired MRSA represents an increasingly frequent cause of cellulitis, and thought should be given to empiric coverage based on local prevalence patterns.
- Risk factors for lower-leg streptococcal cellulitis have been evaluated in large studies. Combining studies suggests the following risk factors in order of importance: lymphedema, other chronic edema, potential breaks in skin integrity (tinea pedis, dermatitis, wounds), venous insufficiency, and (variably) obesity.
- Adequate-dose flucloxacillin is a suitable initial treatment for presumed streptococcal infection, which accounts for most cases. It also covers staphylococci. Selected cephalosporins are more commonly used for IV home treatment, as they can be administered once daily.
- Risk factors for cellulitis are well documented, but evidence to support secondary prophylaxis is only moderate, and for primary prophylaxis is minimal. Factors to predict or identify complications are well established, but most have greater sensitivity than specificity.
- Numerous local and national guidelines for treating cellulitis have been developed. However, the range of potential organisms, introduction of new antibiotics, differences between body sites in terms of risk factors and likely organism, different clinical scenarios (e.g., presence of lymphedema, wounds), the limited evidence for several scenarios, and the noninferiority methodology of many studies, limit the interpretation of the evidence base in this disorder.
- Further studies are required on the role of systemic antibiotics, physical treatments, and compression bandaging and hosiery for acute management and for prophylaxis.

<sup>2</sup>Department of Dermatology, University of Toronto, Toronto, ON, USA

## Background

### Definitions

Exanthem, originating from the Greek word for efflorescence and derived from *anthos* or flower (*Stedman's Medical Dictionary*), is defined as any eruptive skin rash that may be associated with fever or other constitutional symptoms [1]. This may be the result of an infectious disease, as an adverse drug reaction, or by interaction between viruses and drugs. Viral infections are frequently associated with the development of exanthems, especially in the pediatric population. These virally induced exanthems are generally nonspecific and often lack characteristic morphologic or distributive features. Some viral exanthems may be associated with enanthems (an eruption of the mucous membrane). Exanthems can include erythematous, vesicular, and petechial types, although most viral exanthems are erythematous papules and macules (Table 47.1). For the purpose of this chapter, an exanthem will not include urticarial, vesicular, blistering, or purpuric lesions. Many of the viral exanthems are associated with low-grade fever, myalgias, headache, rhinorrhea, or gastrointestinal symptoms. Owing to the large number of viral exanthems, the scope of this chapter will be limited to measles, rubella, hand-foot-and-mouth disease, erythema infectiosum, and roseola infantum.

Drug-induced exanthems are often described as maculopapular, scarlatiniform, or morbilliform eruptions. Because of their nonspecific nature, some clinicians frequently use the generic term “drug rash” to depict these cutaneous eruptions. These eruptions manifest as generalized erythematous changes in the skin without evidence of blistering or pustulation. Pruritus is the most frequently associated symptom. In general, these eruptions are observed within the first 10 days of therapy and resolve within 7–14 days. Resolution occurs with a change in color from bright red to a brownish-red, which may be followed by scaling or desquamation. The differential diagnosis in these patients includes a viral exanthem, collagen vascular disease, and bacterial and rickettsial infections. Drug rash with eosinophilia and systemic symptoms (DRESS) – also known as drug hypersensitivity syndrome reaction (HSR) or drug-induced hypersensitivity syndrome (DIHS) – is a complex drug reaction that can affect various organ systems. Fever, skin eruption (usually

an exanthematous eruption), eosinophilia, and internal organ involvement signal this potentially life-threatening syndrome.

### Incidence/prevalence

Infectious agents were identified in 65% of children with acute febrile illness and rash; of these, 72% of cases were caused by viruses and 20% by bacteria [2]. Infection with parvovirus B19 is ubiquitous and occurs worldwide, most commonly in school-aged children [3]. The seroprevalence of parvovirus B19 antibodies increases with direct proportion to age: 2–15% of children 1–5 years of age are immune, 15–60% between 5 and 19 years, and 30–80% of adults [4]. Hand-foot-and-mouth disease is highly contagious, with epidemics occurring every 3 years in the USA. Human herpesvirus (HHV)-6 primarily affects children between the ages of 6 months and 2 years, with the peak age of acquisition between 9 and 21 months. One study concluded that, by 12 months, two-thirds of children have been infected with HHV-6, with peak antibody levels reached at 2–3 years [5]. Furthermore, the seroprevalence for HHV-6 among young adults in the USA reaches almost 100% [6].

Immunization has dramatically reduced the incidence of measles and rubella in developed countries. Routine use of the rubella vaccine has reduced the incidence of rubella in the USA by more than 98%. In addition, routine use of the measles vaccine over the last 30–40 years is estimated to have reduced global measles morbidity and mortality by 74% and 85%, respectively. In the USA, the total number of reported cases of measles during 2001–2003 was 216 [7]. Yet in Africa and Asia, approximately 30 million cases of measles still contribute to almost 900 000 fatalities annually [8].

In the Boston Collaborative Drug Surveillance Program, the prevalence of cutaneous adverse drug reactions in hospitalized patients was 2.2%. Antibiotics were responsible for 7% of detected reactions [9]. Simple exanthematous eruptions are the most common form of drug eruptions, accounting for at least 80% of all skin reactions [10]. In one study of 104 cases, 94% were considered “morbilliform”-type rashes [11].

### Etiology

The classic childhood exanthems include measles, scarlet fever, rubella, erythema infectiosum, exanthema subitum, and chicken

**Table 47.1** Distinctive features of some viral exanthems.

Disease (synonym)	Causative agent	Season of occurrence	Incubation period	Prodrome	Morphology	Duration of rash	Distribution of rash	Associated symptoms
Rubella (German measles, 3-day measles)	RNA virus of Togaviridae family	Spring	14–21 days	Mild fever and respiratory symptoms	Pink macules or papules	1–2 days	Begins on forehead and spreads to trunk and extremities	Lymphadenopathy, splenomegaly
Measles (rubeola)	Paramyxovirus	Winter/spring	10–14 days	High fever, conjunctivitis, cough	Erythematous, discrete, macular and papular rash	3–5 days	Begins on hair line behind ears and over forehead, spreads to trunk	Koplik spots, photophobia
Erythema infectiosum (fifth disease, slapped cheek disease)	Parvovirus B19	Winter/spring	4–14 days	Fever, malaise, headache, coryza	Bright red macular erythema of cheeks, erythematous macular eruption followed by lacy erythema	1–3 weeks	Face, followed by extremities	Aplastic crisis, papular-purpuric syndrome, arthralgia
Roseola infantum (exanthem subitum, sixth disease)	Human herpes virus (HHV)-6 and HHV-7	Spring/fall	9–10 days	High fever for 3–5 days	Rose-pink macules and papules	3–5 days	Trunk, neck, proximal extremities and sometimes face	Mild upper respiratory symptoms, lymphadenopathy, febrile seizures
Hand-foot-and-mouth disease	Enterovirus	Summer/fall	3–6 days	Fever, malaise, abdominal or respiratory symptoms	Vesicular eruption of palms and soles	7–10 days	Hand, foot, mouth	Erosive stomatitis

pox [12]. In addition, there have been more than 50 infectious agents (viral, bacterial, or rickettsial) identified that cause exanthems in children. One study investigated the causes of morbilliform rash in a highly immunized English population. Among 195 children, laboratory confirmation was obtained in 93 cases (48%): parvovirus B19 in 34 (17%), group A streptococcus in 30 (15%), HHV-6 in 11 (6%), enterovirus in nine (5%), adenovirus in seven, (4%), and group C streptococcus in six (3%) [13]. Another study characterized patients, including 108 children and 152 adults, with atypical exanthems; patients with diagnosis of measles, rubella and varicella were excluded. In 201 patients where a causal relationship was established, 47% were due to viruses, 19% due to bacteria, and 32% due to drug. Iatrogenic etiology (i.e., drug-induced) was more prevalent in the winter, whereas infectious etiology, especially from viral infection, was more prevalent in the spring/summer [14].

Measles (rubeola) is a systemic illness caused by a paramyxovirus that is spread by respiratory droplets. Clinical signs and symptoms consist of fever, cough, coryza, conjunctivitis, morbilliform rash, and Koplik spots. Erythematous macules and papules begin at the hairline and behind the ears and spread down the body [15,16].

The enteroviruses, a subgroup of the picornavirus family, cause a variety of different illnesses associated with exanthems. Hand-foot-and-mouth disease, a common and well-recognized entity, is characterized by a vesicular eruption of the palms and soles as well as stomatitis; it is most commonly associated with coxsackievirus A16 or enterovirus 71 [17]. After an incubation of 3–6 days, low-grade fever, malaise, and abdominal or respiratory symptoms are present. Cutaneous lesions appear as pink to red macules or papules in a characteristic linear arrangement.

Roseola infantum (exanthem subitum, sixth disease) is caused by primary infection with HHV-6 and HHV-7. High fever in an otherwise well-appearing child and a rash with defervescence are

classic findings. The exanthem consists of pink macules and papules that spread from the neck down to the trunk and proximal extremities [4]. Erythema infectiosum (fifth disease) is caused by parvovirus B19. After a 3–18-day incubation period, mild symptoms such as fever, malaise and sore throat develop in 20–60% of cases 2 days before the rash. The exanthem has a characteristic “slapped cheek” appearance; erythematous, edematous, confluent plaques appear symmetrically on both cheeks [4]. Manifestations significantly associated with acute parvovirus B19 infection in immunocompetent children were exanthema, anemia, and leukopenia [18]. In healthy adults, parvovirus B19 usually causes a self-limiting febrile illness, accompanied by other features such as polyarthralgia and facial erythema. Clinically significant arthropathy that may persist for weeks to months is found in 50% of adult patients infected with parvovirus B19 [3,19]. Infections in immunocompromised hosts can lead to chronic infection, most often manifested as chronic anemia [4].

Rubella (German measles), caused by the rubella virus, is usually a mild disease consisting of low-grade fever, generalized erythematous macules and papules, which last 3 days, and generalized lymphadenopathy. In adolescents and adults, but not in children, there is a prodromal period with fever, malaise, sore throat, nausea, and anorexia. An enanthem, called Forchheimer spots, consists of petechiae on the hard palate, and may be present in some patients.

Exanthematous eruptions can be caused by many drugs, including the beta-lactams, sulfonamides, nonnucleoside reverse transcriptase inhibitors (e.g., nevirapine), and antiepileptic medications [20]. The incidence of delayed cutaneous eruptions associated with ampicillin or amoxicillin is 9.5% [21]. Exanthematous eruptions can appear 2–3 days after the drug is started, although they most frequently occur after 8–10 days of therapy. Gemifloxacin, a fluoroquinolone, is associated with a mild to moderate self-limiting

maculopapular rash, especially when used beyond 7 days. When used for 5 days for community-acquired respiratory tract infections, the rash rate is typically less than 1.5%, a rate similar to that with other fluoroquinolones [22]. Since most drugs can cause an exanthematous eruption, it is important to obtain a detailed medication history, including over-the-counter preparations and herbal and naturopathic remedies in patients with a history of an adverse drug reaction. New drugs started within the preceding 6 weeks are potential causative agents for most cutaneous eruptions, as are drugs that have been used intermittently. Approximately 10–20% of all exanthematous eruptions in children are considered to be drug induced, whereas 50–70% of exanthematous eruptions in adults are triggered by drugs.

Drugs that have been reported to cause DRESS include the aromatic anticonvulsants (i.e., phenytoin, phenobarbital, oxcarbazepine, and carbamazepine), lamotrigine, sulfonamide antibiotics, dapsone, nitrofurantoin, nevirapine, minocycline, and allopurinol. In a review of 172 published cases, the most frequently associated drug was carbamazepine, followed by allopurinol, lamotrigine, phenobarbital, and sulfasalazine [23]. Although this reaction has been estimated to occur in between 1 in 1000 and 1 in 10000 anticonvulsant and sulfonamide antibiotic exposures, its true incidence is unknown because of variable presentation and inaccurate reporting.

### Prognosis

Many of the viral exanthems are self-limiting conditions. However, some of the viral illnesses can result in significant morbidity and mortality. In the USA, the mortality rate for *measles* is 0.3%, but in developing countries it can reach 1–10%. Complications include pneumonia, croup, diarrhea, acute encephalitis, brain damage, and death from respiratory and neurologic complications. Measles is one of the leading causes of death among young children, mostly in children under 5 years of age [24]. The most frequent complication of *roseola* is febrile seizures. Among 902 children under 3 years of age with primary HHV-6 infection and fever, 149 (16.5%) had a seizure [25]. Approximately 5% of adult patients and 10% of children undergoing chemotherapy for hematological malignancies are persistently infected with the parvovirus B19 virus (*erythema infectiosum*), resulting in severe and even lethal cytopenias [19]. Arthralgia and arthritis are the most common complications following *rubella*, occurring in up to 70% of postpubertal females [26]. Enterovirus 71-mediated *hand-foot-mouth disease* may be accompanied by central nervous system and pulmonary complications [27].

Many of the viral illnesses acquired during pregnancy may result in adverse outcomes for the fetus. When rubella occurs during the first trimester of pregnancy, the infection can result in approximately 50% of fetuses with manifestations of congenital rubella syndrome, which includes congenital heart defects, cataracts, microphthalmia, deafness, microcephaly, and hydrocephalus [28]. Similarly, although rare, hand-foot-and-mouth disease acquired during first trimester of pregnancy may result in spontaneous abortion. Erythema infectiosum acquired during fetal development may be complicated by fetal hydrops secondary to infection of erythroid precursors, hemolysis, severe anemia, tissue anoxia, and high-output failure. Fetal loss was 6.5% in a series of 334 cases, with 0.6% with nonfatal hydrops fetalis [29].

Simple exanthematous eruptions due to medications generally resolve spontaneously without complications or sequelae within 7–14 days. However, DRESS reactions may, in rare cases, result in significant morbidity and even mortality.

### Diagnostic tests

Many viral infections, including hand-foot-and-mouth disease and erythema infectiosum, are straightforward clinical diagnoses. In addition to the clinical presentation of the exanthem and any enanthem, diagnosis is based on the patient's history (e.g., exposure to other infected individuals) and other distinguishing features of the viral infection, such as predilection for certain seasons. However, confirmation of various viral infections can be accomplished via laboratory tests. Viral culture or polymerase chain reaction (PCR)-based tests can be used for diagnosis of enteroviral infection. Rubella can be diagnosed by detection of anti-rubella IgM antibodies, or a fourfold increase in serum IgG levels. Tests for detection of B19 DNA are required in immunocompromised patients who are unable to mount an adequate humoral response. Methods that detect viral particles or viral DNA are amplified by PCR [4]. Detection of serum anti-B19 IgM antibody can also be used when diagnostic confirmation of B19 infection is needed [19]. However, caution is suggested when interpreting serology in immunodeficient individuals and pregnant women, as they may not necessarily be able to mount an antibody response.

In general, skin biopsies are not indicated for diagnosis of viral exanthem, owing to the nonspecific findings. In addition, a biopsy of drug-induced exanthematous eruptions is generally not necessary, as nonspecific changes are usually present that consist of a mild perivascular lymphocytic infiltrate and a few necrotic keratinocytes within the epidermis.

Some exanthematous eruptions can be identified through patch or delayed-reading intradermal skin tests. Immediate prick skin testing for drug-induced exanthematous eruptions is not helpful in most cases, as skin testing is usually reserved for the diagnosis of IgE-mediated reactions. However, skin testing has been used in the confirmation of delayed ampicillin and amoxicillin exanthematous eruptions [30]. Patch testing, using the drug in a suitable concentration, can be used to confirm various delayed type IV reactions, including contact dermatitis and delayed exanthematous eruptions [31]. The overall sensitivity of patch testing is estimated to be 30–60%, which suggests that a negative patch test does not exclude a drug-induced reaction [32]. One study concluded that patch testing was found to be a useful screening tool if the reaction was exanthematous and if antimicrobial, cardiovascular, or antiepileptic drugs were suspected. A positive patch test to one or more drugs was observed in 89 of 826 patients (10.8%), most often to beta-lactams, clindamycin, and trimethoprim [33].

Diagnostic or confirmatory tests are not readily available for patients with the HSR. An in-vitro test employing a mouse hepatic microsomal system is used for research purposes to characterize patients who develop this serious reaction [34]. Because of the severity of the reaction, oral rechallenges and desensitizations are not recommended, as reexposure to the offending agent may cause development of symptoms within 1 day.

Differential diagnosis for drug-induced exanthems includes viral exanthems (e.g., enteroviruses, HHV-6, parvovirus B19, Epstein-Barr virus (EBV)) and other illnesses such as bacterial and rickettsial diseases, graft-versus-host disease and Kawasaki's syndrome [35,36]. It is often difficult to discriminate between a drug-induced morbilliform eruption and a viral exanthem, although the polymorphic nature of the cutaneous eruption favors a drug eruption. Other features that may help distinguish between a drug-induced and a viral eruption include onset of reaction in relationship to drug, history of previous reaction to a medication, exposure to infected individuals with a similar viral infection, and

characteristic appearance of the rash (e.g., “slapped cheek” for erythema infectiosum).

### Aims of treatment

For most viral and drug-induced exanthems, the aims of treatment are supportive and include reduction of fever, relief of pruritus, and/or management of arthralgias. In immunocompromised patients, the aims of treatment include symptomatic management as well as prevention of complications such as pneumonia, encephalitis, and hepatitis. The aims of treatment in patients with DRESS include symptomatic management and prevention of serious complications such as hepatitis, nephritis, or pneumonitis. Desensitization regimens are generally not recommended for non-IgE-mediated reactions (such as exanthematous eruptions, including DRESS); rather, desensitization protocols are used for IgE-mediated reactions such as anaphylaxis [37].

### Relevant outcomes

For viral and drug-induced exanthems:

- fever;
- extent of exanthem;
- arthralgias and other systemic features, such as malaise, nausea/vomiting, diarrhea;
- resolution of symptoms;
- death.

For drug-induced exanthems:

- onset of symptoms, in temporal relationship to initiation of drug therapy;
- internal organ involvement;
- death.

### Methods

The databases of the Cochrane Library to 2012 and Medline between 1968 and August 2012 were searched for the following terms:

- measles, rubella, roseola, exanthema subitum, fifth disease, parvovirus B19, human, erythema infectiosum, hand-foot-and-mouth disease;
- exanthema, drug eruptions, drug hypersensitivity, skin diseases viral, viral exanthem, drug exanthems, skin diseases.

Subheadings used with the search terms, when appropriate, included “chemically induced,” “epidemiology,” “drug therapy,” “diagnosis,” and “treatment.” Other search terms used in combination with the above terms included “pregnancy” (e.g., rubella and pregnancy), “skin tests” (e.g., skin tests and drug eruptions), “ampicillin,” and “infectious mononucleosis.”

## Questions

### What is the pathogenesis for drug-induced exanthems?

Constitutional factors influencing the risk of cutaneous eruption include pharmacogenetic variation in drug-metabolizing enzymes and human leukocyte antigen (HLA) associations. HLA factors may influence the risk of reactions to nevirapine, abacavir, carbamazepine, and allopurinol [38–41]. Allopurinol-induced adverse reactions, including DRESS, Stevens–Johnson syndrome (SJS), and toxic epidermal necrolysis (TEN), have been strongly associated with a genetic predisposition among Han Chinese; the HLA-B\*5801 allele was found to be an important genetic risk factor [38]. A meta-

analysis found a strong and significant association between HLA-B\*5801 and allopurinol-induced SJS/TEN (using matched control: odds ratio [OR], 96.60; 95% confidence interval [CI], 24.49–381;  $P < 0.001$ ) [42]. The HLA-B\*1502 allele is strongly associated in subjects of Chinese/Asian ethnicity with carbamazepine-induced SJS and TEN, but not with nonblistering eruptions such as exanthematous eruptions or DRESS [41,43]. No correlation between HLA-B\*1502 and carbamazepine-induced SJS/TEN has been found in Caucasians [44]. However, the HLA-A\*3101 allele was associated with carbamazepine-induced hypersensitivity reactions among subjects of northern European ancestry [45]. In addition, the HLA-A\*3101 allele had a 60.7% sensitivity and 87.5% specificity when this allele was applied as a risk predictor for carbamazepine-induced cutaneous adverse drug reactions (including SJS/TEN) in the Japanese population [45]. These data suggest that genetic susceptibility is both phenotype and drug specific [46].

Nevirapine has been associated with HSR involving various combinations of fever, hepatitis, or rash. Studies have suggested that HLA-DRB1\*0101 and the CD4 status of a patient may determine susceptibility to nevirapine hypersensitivity [39]. Abacavir is also associated with a potentially life-threatening adverse reaction in approximately 8% of patients initiated on this drug. Studies have shown that there is a strong predictive association between abacavir HSR and HLA-B\*5701 [47].

Many drugs associated with severe idiosyncratic drug reactions are metabolized by the body to form reactive, or toxic, drug products [48]. These reactive products comprise only a small proportion of a drug's metabolites and are usually rapidly detoxified. However, patients with DRESS and TEN/SJS, resulting from treatment with sulfonamide antibiotics and the aromatic anticonvulsants, show increased sensitivity in in-vitro assessments to the oxidative, reactive drug metabolites of these drugs in comparison with control individuals [49].

Acquired factors also alter an individual's risk of drug eruption. Active viral infection and concurrent medications have been shown to alter the frequency of drug-associated eruptions. For example, valproic acid increases the risk of severe cutaneous adverse reactions to lamotrigine, another anticonvulsant [50]. The basis of these interactions and reactions is unknown, but may represent a mixture of factors, including alteration in drug metabolism, drug detoxification, antioxidant defenses, and immune reactivity.

The course and outcome of drug-induced disease are also influenced by host factors. Older age may delay the onset of drug eruptions and has been associated with a higher mortality rate in some severe reactions. A higher mortality rate is also observed in patients with severe reactions with underlying malignancy [51].

Although the underlying pathogenesis for many drug eruptions remains unknown, certain studies have shown that drug-specific T cells play a major role in exanthematous, bullous, and pustular drug reactions [52]. Immunohistochemical studies have shown that the cell infiltrate in drug-induced maculopapular exanthems is mainly composed of CD3<sup>+</sup> T cells (40–70%), with a predominance of CD4<sup>+</sup> cells [53]. Cytotoxic T cells (more CD4 cells than CD8 cells) contribute to the characteristic features of interface dermatitis, such as vacuolar alteration and keratinocyte death [54].

### What are the features of a reaction known as drug rash with eosinophilia and systemic symptoms?

A widespread rash, often an exanthematous eruption, in conjunction with fever, internal organ involvement (e.g., liver, kidney,

central nervous system), and eosinophilia signifies a more serious reaction, known as DRESS. The condition is also known as HSR and as DIHS. This syndrome has been well described for a number of drugs, including anticonvulsants, sulfonamide antibiotics, dapsone, minocycline, and allopurinol. DRESS occurs most frequently on first exposure to the drug, with initial symptoms starting 2–6 weeks after exposure to the drug. In patients with a history of DRESS, reexposure to the offending agent may cause development of symptoms within 1 day. DRESS is not related to dose or serum concentration of the drug.

A mild to high fever ranging from 38 to 40°C and malaise, which can be accompanied by pharyngitis and cervical lymphadenopathy, are the presenting symptoms in most patients. Atypical lymphocytosis with a subsequent prominent eosinophilia may occur during the initial phases of the reaction in many patients. A generalized exanthem occurs in approximately 85% of patients, usually simultaneously with the appearance of the fever or shortly after. Skin manifestations can range from an exanthematous eruption to more serious eruptions, such as exfoliative dermatitis [55]. Conjunctivitis and angioedema of the face may also be present in some patients, especially patients with anticonvulsant-induced HSR. Liver abnormalities, presenting as elevated transaminases, alkaline phosphatase, prothrombin time, and bilirubin, are present in approximately 50% of patients; in some patients, development of severe hepatitis with jaundice may occur. Other organs, such as the kidney (interstitial nephritis, vasculitis), central nervous system (encephalitis, aseptic meningitis), or lungs (interstitial pneumonitis, respiratory distress syndrome, vasculitis) may less commonly be involved. In a report of 27 patients with DRESS, hepatic and hematological involvements were the two most common systemic complications, occurring in 96% and 85%, respectively [56]. Although resolution occurs in most patients upon discontinuation of the offending drug, some patients have flare-ups with fever, skin eruption, or hepatitis that may occur several weeks after drug withdrawal [57]. A small subgroup of patients may become hypothyroid as part of an autoimmune thyroiditis within 2 months of initiation of symptoms [58]. This is characterized by a low thyroxine level, an elevated level of thyroid-stimulating hormone, and thyroid autoantibodies, including antimicrosomal antibodies.

Diagnostic criteria have been developed for DRESS in hospitalized patients: rash plus three of four systemic features (fever, lymphadenopathy, internal organ involvement, hematological abnormalities) [59]. Diagnostic criteria have also been developed by a Japanese consensus group and include maculopapular rash, prolonged clinical symptoms 2 weeks after discontinuation of the causative drug, fever, liver abnormalities, leukocyte abnormalities, lymphadenopathy, and HHV-6 reactivation [57].

Cross-reactions have been reported with the aromatic anticonvulsants. In one study, 75% of a series of patients with anticonvulsant hypersensitivity syndrome to one aromatic anticonvulsant showed in-vitro cross-reactivity to the other two [60]. In addition, in-vitro testing showed that there is a familial occurrence of hypersensitivity to anticonvulsants. Because siblings and other first-degree relatives are at increased risk (perhaps as high as one in four) of developing a similar adverse reaction, counseling of family members is essential. Although lamotrigine is not an aromatic anticonvulsant, there have been several reports documenting a hypersensitivity syndrome associated with its use [61].

Sulfonamide antibiotics are also metabolized to toxic metabolites – namely, hydroxylamines and nitroso compounds [62]. In most people, detoxification of the metabolite occurs. However, DRESS

may occur in patients who are unable to detoxify this metabolite. Other aromatic amines, such as procainamide, dapsone, and acebutolol, are also metabolized to chemically reactive compounds. We recommend that patients who develop symptoms compatible with a sulfonamide hypersensitivity syndrome reaction avoid these aromatic amines, because the potential exists for cross-reactivity [63]. However, cross-reactivity should not necessarily occur between sulfonamide antibiotics and drugs that are not aromatic amines (e.g., sulfonyleureas, thiazide diuretics, furosemide, and acetazolamide) [64].

The differential diagnosis of DRESS includes other cutaneous drug reactions, acute viral infections, lymphoma, and idiopathic hypereosinophilic syndrome. After DRESS has been diagnosed, there are a minimum number of laboratory tests that help to evaluate internal organ involvement, which may be asymptomatic. Liver transaminases, complete blood count, and urinalysis and serum creatinine should be performed at the initial evaluation. In addition, the clinician should be guided by the presence of symptoms, which may suggest specific internal organ involvement (e.g., respiratory symptoms). Thyroid function tests should be measured and repeated after 2–3 months. A skin biopsy may be helpful if the patient has a blistering or a pustular eruption. Unfortunately, readily available diagnostic or confirmatory tests to establish drug causation are not readily available. An in-vitro test using a mouse hepatic microsomal system is used for research purposes to evaluate patients who develop DRESS [34]. Oral rechallenge or desensitization is not recommended, owing to the severity of the DRESS reactions.

There are no controlled trials of treatment in DRESS. Although the role of systemic corticosteroid therapy is controversial, most clinicians would elect to start prednisone at a dosage of 1–2 mg/kg per day if symptoms are severe, although dosages as low as 0.5 mg/kg per day have also been recommended [65]. There are cases of patients who have been treated with ciclosporin [66] or intravenous immunoglobulin (IVIg) [67]. Antihistamines or topical corticosteroids can also be used to alleviate symptoms. Because the risk of DRESS is substantially increased in first-degree relatives of patients who have had DRESS reactions, counseling of family members is a crucial part of the assessment of this syndrome.

### What role do viruses play in the development of drug eruptions?

Various risk factors may contribute to the development of an adverse drug reaction, including genetic predisposition, drug–drug interactions, and viral infections. Viral infections may create biological alterations in the immune system that enhance the risk of adverse drug reactions.

EBV is the cause of most acute infectious mononucleosis syndromes. Patients primarily present with malaise, fever, pharyngitis, and lymphadenopathy. In patients who have infectious mononucleosis, the risk of developing an exanthematous eruption while being treated with an aminopenicillin (e.g., ampicillin) increases from 3–7% to 60–100% [68]. The rash is extensive, maculopapular, pruritic, and usually accompanied by fever. Although the mechanism of the reaction has not been clarified, it does not appear to be IgE-mediated [69]. In fact, the patient with infectious mononucleosis who develops a delayed rash while on an aminopenicillin is not at risk from developing the same reaction when reexposed to the aminopenicillin or any penicillin without a concurrent EBV infection.

Approximately 50–60% of patients with human immunodeficiency virus/acquired immune deficiency syndrome (HIV/AIDS) who are exposed to sulfonamide antibiotics for *Pneumocystis carinii* infection develop adverse reactions such as fever, rash, neutropenia, and hepatitis [70]. In addition to the presence of HIV, the increased prevalence of slow acetylation and altered activity of oxidative metabolic pathways in AIDS patients with acute illnesses may partly explain the increased incidence of adverse reactions in these patients [71,72].

Reactivation of latent viral infection with HHV-6 also appears common in DRESS and may be partly responsible for some of the clinical features and/or course of the disease [57,73–76]. These viral reactivations have been reported in association with recurrence of symptoms more than 2 weeks after the drug was discontinued [76]. Viral infections may act as, or generate the production of, danger signals leading to damaging immune responses to drugs, rather than immune tolerance [77]. Other viruses, including HHV-7, EBV, and cytomegalovirus, can be reactivated during the course of DRESS [78].

### What treatment regimens have been used in patients infected with viral exanthems?

Most viral exanthems are self-limiting conditions that only require symptomatic treatment. This includes the use of antipyretics (e.g., acetaminophen, ibuprofen) and analgesics (i.e., nonsteroidal anti-inflammatory drugs) in cases of arthralgias. For patients with pruritus, relief can be obtained with antihistamines, topical antipruritic lotions (e.g., calamine), or topical corticosteroids.

### Parvovirus B19

Treatment is usually limited to nonsteroidal anti-inflammatory drugs for management of joint complaints [12]. IVIg has been used in the treatment of patients with chronic or persistent infections due to parvovirus B19; this includes children with immunodeficiency syndromes, chemotherapy-induced suppression, transplant patients, and patients with HIV/AIDS [4]. A persistent parvovirus B19 infection responds to a 5-day or 10-day course of IVIg at a dose of 0.4 g/kg of body weight, with a prompt decline in serum viral DNA, accompanied by reticulocytosis and increased hemoglobin levels [3]. IVIg has also been administered at 1 g/kg for 3 days [18]. Intrauterine red-cell transfusions have been used for the treatment of intrauterine infections with fetal hydrops and anemia, although hydrops fetalis may resolve spontaneously [79].

### Human herpesvirus 6

There are no medications available that are specific for HHV-6. Ganciclovir and foscarnet have been used for serious HHV-6 disease in immunocompromised and transplant patients, but there are no randomized trials. One report described two patients treated early with foscarnet for HHV-6 encephalitis after bone-marrow transplantation. Both patients improved on therapy [80,81]. Antiviral prophylaxis with ganciclovir prevented HHV-6 reactivation in six bone-marrow transplant recipients [82].

### Measles

Vitamin A deficiency is a recognized risk factor for severe measles. The protective effect of vitamin A on measles mortality was shown more than 70 years ago [83]. Measles can decrease serum concentrations of vitamin A in well-nourished children to levels less than those observed in malnourished children without measles. Vitamin A deficiency depresses the immune function and can destroy epi-

thelial tissue; therefore, vitamin A may prevent the complications of measles infection by stimulating the body's impaired immune reaction, by a direct activating effect on helper T cells and by boosting immunoglobulin production [84].

In 1997, the World Health Organization and United Nations Children's Fund (UNICEF) recommended that 200 000 IU of vitamin A should be given twice to children with measles over the age of 1 year in populations in which vitamin A deficiency may be present. If there is clinical evidence or great risk for vitamin A deficiency, the dose is repeated after 4 weeks [85]. The American Academy of Pediatrics suggests that vitamin A be administered to patients aged 2 years or less who are hospitalized with measles and its complications [86]. It should also be administered to patients who are older than 6 months but have an immunodeficiency, ophthalmological evidence of vitamin A deficiency, impaired intestinal absorption, moderate to severe malnutrition, or recent immigration from areas where a high mortality rate from measles has been observed.

There have been several meta-analyses that have evaluated whether vitamin A is beneficial in preventing mortality, pneumonia, and other secondary infections in children with measles [83,85]. In the Cochrane review, eight trials met the inclusion criteria. Overall, there was no significant reduction in the risk of mortality in the vitamin A group when the studies were pooled using the random-effects model (relative risk [RR], 0.70; 95% CI, 0.42–1.15). However, two doses of vitamin A 200 000 IU on consecutive days were associated with a reduction in the risk of mortality in children under the age of 2 years (RR, 0.18; 95% CI, 0.03–0.61) and a reduction in the risk of pneumonia-specific mortality (RR, 0.33; 95% CI, 0.08–0.92). There was no evidence that vitamin A in a single dose reduced the risk of mortality. There was a decrease in the incidence of croup, but no significant reduction in the incidence of pneumonia or diarrhea with two doses [83]. Another meta-analysis evaluated whether vitamin A supplementation in children prevents blindness, although no studies were found that examined the efficacy of vitamin A in preventing blindness [87].

In spite of the possible role of oxidative stress in conditions such as viral infections, vitamins E and C have not been shown to provide any benefit in the course of the illness in children with measles and pneumonia [88]. Studies evaluating the efficacy and safety of Chinese medicinal herbs were systematically reviewed in a Cochrane review; unfortunately, none of the trials concealed the allocation or blinding method, and therefore no analyses were performed [89]. There is no specific antiviral therapy for measles, although ribavirin has been used in patients with measles with severe manifestations [90].

A meta-analysis was done to assess the effects of antibiotics given to children with measles to prevent complications and reduce pneumonia. Seven trials that included 1263 children were included. Although the data showed that the incidence of pneumonia was lower in the treatment group compared with the control group, the difference was not statistically significant. However, eliminating a trial that was conducted in 1942, a statistically significant reduction in the incidence of pneumonia was observed in children receiving antibiotics (OR, 0.26; 95% CI, 0.12–0.60) [91].

### Hand-foot-and-mouth disease

Acyclovir has been studied in the treatment of hand-foot-and-mouth disease in a preliminary report. Symptomatic relief, defer-escence, and significant involution of lesions were seen within 12 h of starting acyclovir (200–300 mg five times daily for 5 days) [92].

In another report, an immunocompromised 27-year-old man with a prolonged course of hand-foot-and-mouth disease was started on oral acyclovir 200 mg five times daily, with subsequent resolution of all lesions within 5 days [93].

### Key points

- Most drug-induced exanthems manifest as generalized erythematous changes in the skin without evidence of blistering or pustulation. Pruritus is the most frequently associated symptom. These eruptions generally occur within the first 10 days of therapy and resolve within 7–14 days after discontinuation of the medication.
- Many of the viral illnesses acquired during pregnancy may result in adverse outcomes for the fetus. For example, when rubella occurs during the first trimester of pregnancy, the infection can result in approximately 50% of fetuses with manifestations of congenital rubella syndrome.
- Diagnosis of viral infections includes the clinical presentation of the exanthem and enanthem, and the patient's history (e.g., exposure to other infected individuals and distinguishing features of the viral infection). Laboratory tests can be done for confirmation, if necessary.
- Diagnosis of drug-induced exanthematous eruptions is based on the clinical history. The use of confirmatory tests, such as patch or delayed reading of intradermal skin tests, has not been well defined.
- The aims of treatment for most viral and drug-induced exanthems are supportive and include reduction of fever, relief of pruritus, and/or management of arthralgias.
- Factors that may influence the risk of a cutaneous eruption include pharmacogenetic variation in drug-metabolizing enzymes and HLA associations, acquired factors (e.g., active viral infection and concurrent medications), host factors (e.g., age, underlying malignancy), and drug-specific T cells.
- DRESS is comprised of a cutaneous eruption (usually exanthematous), fever, eosinophilia, and internal organ involvement. This reaction usually occurs on first exposure to the drug, with initial symptoms starting 2–6 weeks after exposure to the drug. This reaction is most commonly associated with the aromatic anticonvulsants (phenytoin, phenobarbital, carbamazepine), sulfonamide antibiotics, allopurinol, dapsone, and minocycline.

# Herpes simplex

Vera Mahler

Department of Dermatology, University Hospital Erlangen, Erlangen, Germany

## Background

### Definition

Herpes simplex virus (HSV) is a human pathogenic DNA virus that causes a variety of disease manifestations, ranging from localized skin and mucous membrane lesions to severe disseminated infections (such as neonatal herpes simplex, eczema herpeticum, and herpetic meningoencephalitis). The infection is frequently acquired in an occult manner or it may present as primary herpetic gingivostomatitis, which can include oral as well as extraoral lesions, swollen and bleeding gums, pain, fever, irritability, malaise, headache, and upper respiratory tract infection [1]. Following the primary infection, the virus resides in the sensory ganglia in a latent form. Upon reactivation, symptomatic recurrent lesions or asymptomatic virus shedding occurs.

In recurrent manifestations, grouped vesicles are predominantly located at the lips and nostrils, in the mouth and face, and on the genitals. They may rupture and ulcerate. Lesions are accompanied by pain and/or itching, and in genital lesions also with dysuria and malaise.

### Etiology

HSV infections are transmitted by two virus species, HSV-1 and HSV-2, belonging to the group of double-stranded DNA-type viruses (Herpesviridae family, subfamily Alphaherpesvirinae, genus *Simplexvirus*) (Figures 48.1 and 48.2). HSV-1 is still most frequently transmitted by saliva and HSV-2 by genital transmission [2–4], although these findings are no longer reliable in individual cases. Infection is contracted through direct skin contact (not necessarily in the genital area) with an infected person, and less frequently by indirect contact. Transmission can occur not only during an active symptomatic HSV manifestation, but also from virus shedding from the skin in the absence of symptoms [5,6]. The peak viral DNA load has been reported to occur after 48 h, with no virus detected beyond 96 h after the onset of symptoms [7]. In general, symptoms appear 3–6 days after contact with the virus, but may not appear for up to a month or more after infection.

### Incidence/prevalence

HSV-1 infection frequently occurs during childhood, and over 90% of adolescents have specific antibodies in their sera indicating a previous primary (maybe occult) infection. Only 5–10% of patients initially infected with the HSV develop clinical lesions of a primary herpetic gingivostomatitis [1]. The lifetime prevalence of recurrent herpes labialis is 20–40% [8].

For HSV-2, there is an increasing prevalence of about 20% from the age of puberty onward [2,4]. Symptomatic recurrent flares occur in 20–50% of patients who have anti-HSV antibodies. Following a symptomatic first episode of HSV-2 genital infection a median recurrences rate is of four recurrences during the first year. The rate of recurrence usually decreases over time, but in about one-quarter of the patients it increases [9].

### Prognosis

Active localized manifestations heal spontaneously within 2–6 weeks without scarring, unless bacterial superinfection has occurred. However, herpes simplex establishes a latent infection in cells of the nervous system by incorporation of double-stranded DNA into the cell nucleus, which can be reactivated by certain trigger factors (e.g., febrile infections, trauma, menstruation, stress, intense ultraviolet exposure). Disseminated systemic disease may be fatal.

### Diagnostic tests

In most cases, the diagnosis is based on the characteristic clinical appearance of lesions. In uncertain cases, diagnostic tests and proof of virus can be necessary. HSV can be grown in virus culture from vesicles, swabs from skin and mucous membranes, tissue biopsies, and cerebrospinal fluid (during the first 2 days of disease manifestation). Whereas these tests take several days to complete, a Tzanck smear from the base of a fresh blister takes only minutes. However, the Tzanck preparation only shows signs of infection (giant cells with multiple nuclei) in 50–79% of patients with a herpes infection, and a negative Tzanck preparation may have to be confirmed by a herpes culture. Detection of HSV antigen (by direct

**Figure 48.1** HSV-1 infection most frequently presents orally and at the lips. Recalcitrant recurrences of labial herpes (HSV-1) may be triggered by a variety of factors. The painful and visible lesions often cause severe discomfort in the patient seeking for medical advice.

**Figure 48.2** HSV-2 infection presents most frequently as genital herpes. Lesions are accompanied by pain and/or itching, and sometimes dysuria and malaise. Recalcitrant recurrences may severely hamper the quality of life.

immunofluorescence) or HSV DNA (by polymerase chain reaction) are further diagnostic tests for valid diagnosis of HSV infection. In individuals with a primary HSV infection, specific IgM antibodies can be detected after 10 days (e.g., using a Western blot assay), followed by a subsequent increase in IgG antibodies. Reactivation cannot be adequately confirmed serologically.

### Aims of treatment

Episodes of active disease are self-limiting in the immunocompetent adult. However, many patients with primary and recurrent

genital and extragenital herpes simplex may seek treatment because of discomfort associated with the lesions during active disease, the virus shedding, and the duration of the condition.

### Relevant outcomes

Clinical cure of active lesions is the clinically most relevant outcome. Treatment success is defined as shortening of the duration of pain, active lesions, and virus shedding. Secondary outcomes include time to recurrence and reactivation of latent infection.

### Methods of search

The Cochrane Library for Systematic Reviews (January 2013), the Cochrane Controlled Trials Register (January 2013) and Medline (1966–January 2013) were searched for systematic reviews of randomized controlled trials (RCTs) and high-quality individual RCTs of all interventions for primary and secondary herpes simplex infections in immunocompetent adults.

If no systematic reviews or RCTs were found, this is stated and the next best evidence (e.g., large nonrandomized controlled studies, cohort studies, or large case series) is discussed with suitable warnings regarding potential bias.

### Questions

#### Which treatment in primary manifestation of an oral/labial herpes simplex is beneficial with regard to total lesion clearance in the immunocompetent adult?

##### Efficacy

No systematic review or individual RCTs were found on therapeutic interventions with *topical* antiviral agents versus placebo/no treatment at first onset of a primary oral manifestation of HSV in immunocompetent adults.

A Cochrane systematic review (CSR) on *systemic* aciclovir in the treatment of primary herpetic gingivostomatitis in children and young adults (under the age of 25) has been published [1].

Only two RCTs, one with 72 participants and the other with 20 participants, were included in this review. The second study failed to report several methodological items and was inconsistent in its reporting of the outcomes measurement [1].

The first trial, with a moderate risk of bias, showed better results in the aciclovir group (15 mg/kg five times per day for 7 days started within 3 days after onset of herpetic gingivostomatitis) compared with the placebo group in children <6 years of age: in reducing the number of individuals with oral lesions (risk ratio [RR], 0.10; 95% confidence interval [CI], 0.02–0.38), new extraoral lesions (RR, 0.04; 95% CI, 0.00–0.65), difficulty in eating (RR, 0.14; 95% CI, 0.03–0.58), and drinking difficulties (RR, 0.11; 95% CI, 0.01–0.83) after 8 days of treatment. The time to healing was significantly shorter in the children receiving aciclovir (median: 4 days; range: 2–12 days) than in those receiving placebo (median: 10 days; range: 3–15 days) [1].

The second double-blind RCT in 20 children with a mean age of 2 years with a primary manifestation of herpetic stomatitis/gingivitis of less than 4 days' duration compared oral aciclovir (200 mg five times per day) with placebo. Active treatment reduced the mean duration of pain (4.3 days with aciclovir vs 5.0 days with placebo;  $P = 0.05$ ), however, details of pain assessment in this age group are unavailable.

## Drawbacks

No significant adverse effects occurred in either group of treated children [1].

## Comments

The data are derived from two trials conducted in children. No RCTs on interventions for a primary manifestation of an oral/labial herpes simplex infection in the immunocompetent adults were found. There is a need for trials to be conducted in other age groups.

## Implications for clinical practice

On the basis of data obtained in affected children, oral antiviral agents (aciclovir) are likely to be beneficial in the first onset of oral/labial herpes simplex. Topical antiviral agents are of unknown effectiveness for primary manifestations of oral/labial herpes simplex in the immunocompetent adult.

## Which therapeutic interventions are beneficial for preventing recurrences of labial herpes simplex in immunocompetent adults?

### Efficacy

No systematic review is currently available. A protocol for a CSR on any systemic, topical, or physical intervention used for the prevention of recurrent labial herpes simplex (HSL) in immunocompetent individuals has been registered (dated 2012) [10].

To date, six RCTs were found on the suppression of oral recurrences in immunocompetent adults by prophylactic intake of oral antiviral agents [11–15]. Their results are discordant.

The first RCT observed a reduction in the frequency and duration of labial recurrences in skiers ( $n = 147$ ) with a history of ultraviolet-precipitated HSL using prophylactic oral aciclovir (400 mg twice daily, beginning 12 h *before* ultraviolet exposure) in comparison with placebo ( $P < 0.05$ ) [11]. Five of 75 aciclovir-treated patients (7%) developed lesions, in comparison with 19 (26%) of 72 persons in the placebo group.

The second, rather small RCT (20 individuals with at least six episodes of HSL/year) found that aciclovir (400 mg twice daily for 4 months) led to 53% fewer clinical recurrences than placebo ( $P = 0.05$ ) and a more than 2.5-fold greater prolongation in the median time to first clinical recurrence (46–118 days;  $P = 0.05$ ) [12].

The pooled analysis of two further RCTs [13] (98 adults with at least four episodes of HSL in the previous year) found that oral valaciclovir 500 mg daily significantly increased the interval to recurrence in comparison with placebo (no recurrence within 4 months: 62% with oral valaciclovir vs 40% with placebo;  $P = 0.041$ ; mean time to recurrence 13.1 weeks with oral valaciclovir vs 9.6 weeks with placebo;  $P = 0.016$ ).

In contrast, two RCTs found no effect of prophylactic antiviral treatment. In 239 skiers with a history of recurrent HSL, no significant differences were observed with regard to the occurrence of herpetic lesions between the active treatment group (800 mg aciclovir twice daily, starting on the day *before* ultraviolet exposure) in comparison with the placebo group – 21 of 93 (23%) with aciclovir versus 21 of 102 (21%) with placebo ( $P = 0.92$ ; 95% CI, not stated) [14].

In another RCT including 248 adults with a history of sun-induced recurrent HSL, famciclovir was administered in different regimens (125, 250, or 500 mg three times a day for 5 days, beginning 48 h *after* artificial ultraviolet exposure) in comparison with placebo [15]. No significant differences were found between the

four groups with regard to numbers of lesions ( $P$  value not reported). However, a dose–response relationship was found between increasing doses of famciclovir and significantly reduced size and duration of the lesions: Only the 500 mg regimen significantly reduced the mean time to healing by 2 days (4 vs 6 days, 33% reduction;  $P = 0.01$ ) and the size of lesions (mean size of lesions;  $P = 0.04$ ; mean time to healing:  $P = 0.01$ ).

A double-blind RCT found that L-lysine monohydrochloride (assumed antiviral activity due to its antagonism of arginine metabolism required in HSV replication) was ineffective administered at daily doses of 624 mg orally, but effective with regard to the recurrence rates when administered at high oral dosages (1248 mg/day). During the treatment period of 24 weeks, 0.89 recurrences per patient (i.e., 0.037 per patient per week) occurred during high-dose treatment, 1.56 recurrences per patient (i.e., 0.065 recurrences per patient per week) during placebo treatment, and 2.27 recurrences per patient (0.095 recurrences per patient and week) in the low-dose treatment [16]. The duration of symptoms was similar to placebo [16].

## Drawbacks

Mild to moderate headache and nausea were the most common adverse effects reported of antiviral treatment. The second RCT provided no information about adverse effects [12]. None of the other RCTs [11–15] found significant differences in frequency or severity of adverse events with the used antiviral drug and placebo.

## Comments

The participants in one RCT were allowed to use paracetamol as concomitant medication and were encouraged to use sunscreens [14]. Sunscreens could be a confounder with the effects of aciclovir in this study, since sunscreens per se could have a preventive effect on herpetic recurrences. A systematic review on this issue was not found. Two small crossover RCTs are available [17,18]. Both found that sunscreen significantly reduced recurrences in individuals with a history of ultraviolet-induced reactivation at 6 days in comparison with placebo: (i) no recurrences occurred in 35 patients with sunscreen versus 27 of 38 (71%) with placebo ( $P < 0.001$ ) [17]; (ii) at a defined UV dose, one recurrence occurred in 19 individuals (5%) with sunscreen versus 11 of 19 (58%) with placebo ( $P < 0.01$ ) [18].

## Implications for clinical practice

Oral antiviral agents, as well as the use of sunscreens, are likely to be beneficial for prevention of labial recurrences. Prophylactic oral antiviral agents may reduce the frequency and severity of attacks in comparison with placebo [11–15]. However, the optimal timing and duration of treatment is uncertain. Topical antivirals are of unknown effectiveness, since no RCTs are available on the effects of prophylactic use of topical antiviral agents.

## Which treatments are effective in treating recurrent oral/labial herpes simplex in the immunocompetent adult?

### Efficacy

A systematic review is currently unavailable. A protocol for a CSR on interventions for treatment of HSL has been registered (dated 2011). Its objective is to review any topical or systemic agents or physical interventions used therapeutically for HSL, in different doses, frequency, and duration of administration. The control may be a placebo, no treatment, or another active intervention [19].

A number of individual RCTs are available both for topical and for systemic treatment of labial recurrences.

### Topical treatment of recurrences

Several RCTs are available on topical aciclovir/penciclovir versus placebo for treatment of clinical manifestations of recurrent HSL in immunocompetent adults [20–30]. Most RCTs found that aciclovir significantly reduced healing time up to 2 days in comparison with placebo (median value to complete healing in placebo: 8 days vs 6 days with aciclovir) [21,22,25–28]. In a small RCT ( $n = 15$ ) with a crossover design, aciclovir in liposomes significantly reduced the time to crusting of lesions in comparison with aciclovir cream (1.8 days vs 3.5 days;  $P = 0.023$ ) [30]. One RCT found no significant difference in healing time between topical aciclovir and placebo [23].

Four RCTs found no significant differences in the duration of pain between aciclovir and placebo [20–23,25], whereas one large RCT on treatment with penciclovir showed a significantly reduced duration of pain (median 3.5 days with penciclovir vs 4.1 days with placebo;  $P < 0.001$ ) [24], as well as a reduced healing time of up to 2 days [24,27].

The combination of 5% aciclovir and 1% hydrocortisone (ME 609; Xerese™; FDA approved since 2009) applied five times per day for 5 days showed a significant benefit in prevention of ulcerative lesion in HSL in an RCT with  $n = 2437$  enrolled patients with a history of recurrent labial herpes [31]. A total of 1443 patients experienced a recurrence and initiated the treatment. Of patients receiving the aciclovir–hydrocortisone combination ( $n = 601$ ), 42% did not develop an ulcerative lesion compared with 35% of patients ( $n = 610$ ) receiving aciclovir ( $P = 0.014$ ) and 26% of patients ( $n = 232$ ) receiving placebo ( $P < 0.0001$ ). Healing times of ulcerative lesions were reduced in the aciclovir–hydrocortisone and aciclovir groups compared with placebo ( $P < 0.01$  for both). The cumulative lesion area for all lesions was reduced 50% in patients receiving the aciclovir–hydrocortisone combination compared with the placebo group ( $P < 0.0001$ ). There were no differences among groups in the number of patients with positive HSV cultures. The side-effect profile was similar among treatments [31].

Topical preparations other than antiviral agent (e.g., local anesthetics, zinc oxide, 1,5-pentanediol, hydrocolloidal wound dressing) have also been suggested in order to reduce the healing time and duration of pain.

One double-blind RCT ( $n = 72$ ) found that 1.8% tetracaine (amethocaine) cream (applied six times per day) significantly reduced the mean time to loss of crusts (5.1 days with tetracaine vs 7.2 days with placebo;  $P = 0.002$ ) and significantly increased the subjective benefit of treatment [32].

One double-blind RCT ( $n = 46$ ) found that zinc oxide/glycine (applied twice an hour during waking hours from the first signs of the herpetic reactivation) significantly reduced time to healing in comparison with placebo (5.0 days with cream vs 6.5 days with placebo;  $P = 0.018$ ) [33].

In one double-blind RCT in  $n = 105$  patients with HSL recurrences, a 25% 1,5-pentanediol gel applied twice a day versus placebo showed a statistically significant superiority ( $P < 0.001$ ) regarding the healing time of the symptoms blistering, swelling, and pain during recurrences. 1,5-Pentanediol is an emulsifying agent with antiviral properties. There was no significant difference in recurrence rate between the two groups ( $P > 0.05$ ) [34].

One multicenter assessor-blinded study in 728 subjects with a history of recurrent HSL compared the efficacy of topical 5% aciclovir cream (applied five times per day) versus a hydrocolloidal

wound dressing (CSP) [35]. Of 351 individuals who experienced an HSL outbreak,  $n = 179$  were randomized to use CSP and  $n = 172$  aciclovir cream 5% at the onset of symptoms until the lesion healed, for a maximum of 10 days. The primary end point was the subject's global assessment of therapy (SGAT: 0, no response; 10, excellent response). The difference in SGAT (7.89 and 8.00, respectively) and in healing times between products was not significant (median, 7.57 days with CSP vs 7.03 days with aciclovir,  $P = 0.37$ ). Both treatments were well tolerated. CSP-treated subjects reported a higher lesion protection and hygiene and lower visibility.

### Systemic treatment of recurrences

Four RCTs were found on systemic antiviral treatment of recurrences in immunocompetent adults [36–38]. The first (including 174 adults with recurrent herpes labialis) found that oral aciclovir (400 mg five times per day for 5 days), taken from the first signs of recurrence (symptoms of labial tingling), significantly reduced the duration of clinical symptoms in comparison with placebo (8.1 days with oral aciclovir vs 12.5 days with placebo;  $P = 0.02$ ) [36]. The second RCT ( $n = 149$ ) compared oral aciclovir (200 mg five times per day for 5 days) started within 12 h of the recurrence with placebo: no significant differences were found with regard to healing time or duration of pain between oral aciclovir and placebo [37]. Two further RCTs (published in the same paper) compared oral valaciclovir (2 g twice per day administered for 1 day only), oral valaciclovir (2 g twice per day on the first day followed by 1 g twice per day on the second day) and placebo in patients over 12 years of age with a history of recurrent HSL [38]. One of these RCTs ( $n = 902$ ) found that both regimens significantly reduced the median duration of vesicular and nonvesicular lesions in comparison with placebo (4.0 days with 1-day treatment,  $P < 0.001$ ; 4.5 days with 2-day treatment with valaciclovir,  $P < 0.009$ , vs 5.0 days with placebo). The other RCT ( $n = 954$ ) found similar results (5.0 days with 1-day treatment,  $P < 0.001$ ; 5.0 days with 2-day treatment with valaciclovir,  $P < 0.001$ , vs 5.5 days with placebo). Neither RCT found a significant difference between 1-day treatment and 2-day treatment with valaciclovir ( $P$  values not reported).

### Drawbacks

#### Topical treatment

No serious adverse events of topical antiviral agents were reported, and similar rates of minor adverse effects occurred in the active treatment groups and placebo groups [20–31]. No adverse effects were reported as a result of topical treatment with 1.8% tetracaine (amethocaine) cream and 1,5-pentanediol [32]. Transient mild to moderate sensations of burning, itching, stinging, or tingling were reported in up to 22% ( $n = 7$ ) of patients treated with zinc oxide, versus 7% ( $n = 2$ ) with placebo [33]. Mild lip bleeding, erythema, and irritation related to the study medication were reported in 7.5% ( $n = 4/53$ ) of patients treated with the hydrocolloid dressing versus 3.8% ( $n = 2/52$ ) with aciclovir.

#### Systemic treatment

The first two RCTs on oral antiviral treatment provided no information about adverse events [37,38]. In the large third and fourth RCTs [38], headache was more common with valaciclovir than with placebo (third RCT: 9% with 1-day treatment; 9% with 2-day treatment with valaciclovir vs 4% with placebo;  $P$  values not reported; fourth RCT: 10% with 1-day treatment; 9% with 2-day treatment

vs 5% with placebo; *P* values not reported) [38]. The other most common adverse events, nausea and diarrhea, were reported equally in all three treatment groups (1-day treatment with valaciclovir, 2-day treatment with valaciclovir, and placebo).

### Comments

Early treatment after onset of the recurrence is apparently feasible, but no RCTs on early versus delayed intervention are available. Firm conclusions about the most feasible timing of systemic antiviral treatment cannot, therefore, be drawn.

### Implications for clinical practice

Data from a number of RCTs comparing topical antiviral agents with placebo in the treatment of recurrences of HSL show discordant results with regard to the duration of pain, but provide stronger evidence that topical penciclovir, aciclovir, and acyclovir-hydrocortisone reduce the healing time. Healing times differed not significantly between aciclovir and a hydrocolloidal dressing (CSP).

One small RCT found limited evidence that topical tetracaine reduced the mean time to scab loss, another accelerated healing time with pentanediol compared with placebo. One small RCT found limited evidence that zinc oxide cream reduced time to healing, but found a higher proportion of mild skin irritation compared with placebo.

RCTs on the systemic treatment of recurrent episodes of HSL provided limited evidence that oral aciclovir and valaciclovir (if taken early at the first symptoms of recurrence) slightly reduced the duration of lesions and pain in comparison with placebo.

### Which treatments are beneficial in primary manifestations of genital herpes simplex in the immunocompetent adult?

#### Efficacy

A systematic review is not available. Three RCTs compared aciclovir (200 mg five times per day for 10 days [39,40] or 5 days [41]) versus placebo [39]. The first RCT [39] (including 119 individuals with primary manifestation of genital herpes) showed that aciclovir significantly reduced the time to complete healing of lesions (12 days with aciclovir vs 14 days with placebo; *P* = 0.005), reduced the formation of new lesions (18% with aciclovir vs 62% with placebo; *P* = 0.001), reduced the duration of pain (5 days with aciclovir vs 7 days with placebo; *P* = 0.05), and reduced viral shedding in comparison with placebo (2 days with aciclovir vs 9 days with placebo; *P* < 0.001). The second RCT (including 31 individuals with primary manifestation of genital herpes) [41] and third RCT [40] (including 31 women and 17 men) with aciclovir (200 mg five times daily for 10 days) confirmed these results.

A systematic review comparing valaciclovir with aciclovir was not found. One large RCT (including 643 individuals with a first episode of genital herpes) compared oral valaciclovir (1000 mg twice daily for 10 days) with oral aciclovir (200 mg five times daily for 10 days) [42]. It found no significant difference between the treatments with regard to healing time (hazard ratio [HR], 1.08; 95% CI, 0.92–1.27), duration of symptoms (HR, 1.02; 95% CI, 0.85–1.22), and duration of viral shedding (HR, 1.00; 95% CI, 0.84–1.18).

### Drawbacks

Adverse effects were rare and similar in the placebo and treatment groups (aciclovir) [40,41]. In a large RCT, headache occurred in

11.5% and nausea in 5.9% of patients treated with aciclovir [42]. There were no differences with regard to adverse events between the aciclovir and valaciclovir groups.

### Comments

In one of the RCTs [39], 30 of 180 participants (17%) were excluded before analysis: 10 because the study protocol was not completed, 12 due to suspected previous infection, and eight because HSV was not isolated [39]. Famciclovir is also recommended for the first clinical episode of genital herpes according to expert guidelines [43].

### Implications for clinical practice

Oral antiviral treatment with aciclovir/valaciclovir in patients with a primary manifestation of genital herpes is effective with regard to the duration of lesions, symptoms, and viral shedding in comparison with placebo. One large RCT found no differences in clinical outcomes between oral aciclovir and valaciclovir.

### Which medical interventions are effective in preventing recurrences of genital herpes simplex in immunocompetent adults?

#### Efficacy

Currently, there is no systematic review, but there is a protocol for a CSR available on oral antiviral therapy for prevention of genital herpes outbreaks in immunocompetent and nonpregnant patients (dated from 2011) [9]. Its objectives are to review suppressive oral antiviral treatment of genital herpes with oral aciclovir, famciclovir, or valaciclovir compared with placebo or an antiviral treatment with regard to rate of recurrent episodes of genital herpes and recurrence-free survival as primary outcomes [9].

Based on numerous RCTs, several oral antiviral agents have been suggested for prophylaxis against the reactivation of genital herpes.

#### Aciclovir versus placebo

One nonsystematic review based on two RCTs (*P* = 107) [44] found in the first RCT (*n* = 32) that aciclovir (800 mg/day) reduced recurrences in comparison with placebo at 2 years – no recurrence at 2 years: five of 18 (28%) with aciclovir versus none of 14 (0%) with placebo; absolute risk reduction (ARR), 28% (95% CI, 1–51%) [44]. In the second RCT (*n* = 75), aciclovir (400 mg twice per day) also reduced recurrences in comparison with placebo at 1 year – no recurrence at 1 year: 21 of 48 (44%) with aciclovir versus none of 28 (0%) with placebo (ARR, 44%; 95% CI, 26–56%).

Four other RCTs [45–48] comparing aciclovir (400 mg twice per day) with placebo gained concordant results:

- 1 *n* = 1479 participants – no recurrence at 1 year: 49% with aciclovir versus 5% with placebo; HR, 0.21; 95% CI, 0.16–0.27 [45].
- 2 *n* = 1146 participants – recurrence rate at 1 year: 1.7% with aciclovir versus 12.5% with placebo; *P* < 0.0001 [46]; *n* = 210 participants with continuous aciclovir treatment for 5 years – 53–70% of patients were free of recurrence each year [46].
- 3 *n* = 32 women – aciclovir (for 70 days) reduced viral shedding in comparison with placebo by 95% on days with reported lesions and by 94% on days without lesions [47].
- 4 The fourth RCT (*n* = 1479) [48] compared the suppressive effects of antiviral agents administered once or twice per day in a six-armed protocol (valaciclovir 1000 mg once per day; valaciclovir 500 mg once per day; valaciclovir 250 mg once per day; valaciclovir 250 mg twice per day; aciclovir 400 mg twice per day;

or placebo) with regard to quality of life [49]. All treatment groups (and aciclovir most) significantly improved the health-related quality of life in comparison with placebo after 3 months ( $P < 0.05$ ) [48].

A recent RCT in a total of 3127 evaluable HSV-2-seropositive, HIV-negative, participants enrolled in the USA, Peru, and Africa comparing aciclovir suppressive therapy (400 mg twice per day) with placebo found reduced HSV-2-associated genital ulcer disease and lesional HSV shedding. Aciclovir had a significantly smaller effect on the frequency of genital ulcer disease as well as a smaller effect on the frequency and quantity of lesional HSV DNA in African women and Peruvian men, compared with its effects in men in the USA ( $P < 0.001$ ) [50]. Virus strain variation, differences in aciclovir absorption, or pharmacokinetics may be responsible for these differences. Further studies are required for elucidation of causes and optimization of antiviral prevention of recurrences in these populations.

### **Valaciclovir versus placebo**

One systematic review (published in 1999; search date not reported) [51] based on two RCTs ( $n = 1861$ ) compared suppressive treatment with valaciclovir versus placebo for frequently recurring genital herpes. The first RCT included in the review ( $n = 382$ ) found that valaciclovir (500 mg once per day for 16 weeks) significantly increased the time to recurrence in comparison with placebo (HR, 0.10; 95% CI, 0.11–0.21) [51]. At 16 weeks, 69% of the valaciclovir recipients were recurrence free, in comparison with 9.5% of placebo recipients.

The second RCT ( $n = 1479$  people) compared the suppressive effects of valaciclovir administered once or twice per day in a six-armed protocol (valaciclovir 1000 mg once per day; valaciclovir 500 mg once per day; valaciclovir 250 mg once per day; valaciclovir 250 mg twice per day; aciclovir 400 mg twice per day) versus placebo at 1 year. A dose-dependent effect of valaciclovir was observed in relation to freedom from recurrence in comparison with placebo. Subgroup analysis showed that patients with a history of less than 10 recurrences per year were effectively managed with 500 mg of valaciclovir once daily. One gram of valaciclovir once daily, 250 mg of valaciclovir twice daily, or 400 mg of aciclovir twice daily were more effective in patients with 10 or more recurrences per year. Suppressive treatment with valaciclovir (once or twice daily) significantly improved health-related quality of life in comparison with placebo after 3 months (as measured using a recurrent genital herpes quality-of-life questionnaire;  $P < 0.05$ ) [48,49].

An RCT ( $n = 152$ ;  $n = 109$  receiving valaciclovir 1 g/day vs 43 receiving placebo for 60 days) demonstrated in the intention-to-treat population a 71% reduction in total shedding ( $P < 0.001$ ), a 58% reduction in subclinical shedding ( $P < 0.001$ ), and a 64% reduction in clinical shedding ( $P < 0.01$ ) [52].

Two recent RCTs studied suppressive therapy (valaciclovir 1 g/day vs placebo for 6 months) during the *first year after acquisition* of genital herpes, the time of maximum frequency of reactivation, potential for transmission, and impact on quality of life. The intention-to-treat analysis of the first of the two studies ( $n = 119$  participants enrolled in two centers in the USA) analyzed rates of symptomatic recurrences for valaciclovir and placebo. These were  $1.7 \pm 2.7$  (mean plus/minus standard deviation) and  $3.4 \pm 4.0$  outbreaks per year ( $P = 0.012$ ). Time to first recurrence was  $80 \pm 47$  days for valaciclovir and  $54 \pm 49$  days for placebo ( $P = 0.001$ ). The differences in favor of valaciclovir were greatest in patients with confirmed HSV-2 infection. The Recurrent Genital Herpes Quality

of Life score in HSV-2-infected patients rose  $11.9 \pm 11.1$  points for valaciclovir and  $5.9 \pm 9.1$  points for placebo ( $P = 0.040$ ) [53].

The second RCT with  $n = 384$  subjects enrolled in 75 centers in the USA, Canada, Argentina, Brazil, and Chile confirmed these findings: 43% of subjects on placebo and 71% of subjects on valaciclovir were recurrence free at 24 weeks ( $P < 0.001$ ), mean number of recurrences per month was 0.11 for valaciclovir and 0.48 for placebo,  $P < 0.001$ . Adverse events were comparable in the valaciclovir and placebo arms [54].

### **Famciclovir versus placebo**

One systematic review [51] based on two RCTs ( $n = 830$ ) found that famciclovir significantly increased the median time to first recurrence in comparison with placebo. In the first RCT ( $n = 455$ ), famciclovir (250 mg twice per day, 125 mg three times per day, or 250 mg three times per day for 1 year) increased the median time to first recurrence significantly in comparison with placebo (11 months with famciclovir 250 mg twice per day, vs 10 months with famciclovir 250 mg three times per day, vs 8 months with famciclovir 125 mg three times per day, vs 1.5 months with placebo). In the second RCT ( $n = 375$ ), female recipients received famciclovir (125 mg twice per day, 125 mg four times per day, 250 mg twice per day, 250 mg four times per day, or 500 mg four times per day, or placebo for 4 months). Famciclovir 250 mg twice per day was found to be the most effective dosage for reducing recurrences [51]. In comparison with placebo, significant numbers of famciclovir recipients were free of recurrences at 4 months (78% with 250 mg twice per day vs 42% with placebo).

### **Valaciclovir versus famciclovir**

Two RCTs compared famciclovir (250 mg b.i.d.) and valaciclovir (500 mg/day) administered as daily suppressive therapy for individuals with genital herpes [55]. Study 1 (including 320 participants) compared the clinical effect of the drugs given for 16 weeks; study 2 compared the virological effect of the drugs given for 10 days in 70 HSV-2-seropositive patients. In study 1, the time to first recurrence was similar in the famciclovir and valaciclovir recipients, with an HR of 1.17 (95% CI, 0.78–1.76), but the time to the first virologically confirmed recurrence was shorter among famciclovir recipients (HR, 2.15; 95% CI, 1.00–4.60). In study 2, HSV was detected on 3.2% of days among famciclovir recipients and 1.3% of days among valaciclovir recipients (relative risk, 2.33; 95% CI, 1.18–4.89) [55].

### **Drawbacks**

Daily treatments with aciclovir, famciclovir, and valaciclovir were well tolerated [45,56]. The safety profiles of all of the treatments were comparable.

The aciclovir recipients were followed for up to 7 years, and the famciclovir and valaciclovir recipients for up to 1 year [56]. Nausea and headache were infrequent, and participants rarely discontinued treatment due to adverse effects. No evidence was found that suppressive daily treatment with aciclovir results in the development of aciclovir resistance during or after stopping treatment in healthy adults [56].

### **Comments**

Further comparative trials of antiviral drugs for the suppression of genital herpes recurrences should be conducted, as aciclovir and penciclovir appear to have different abilities to abrogate HSV reactivation.

### Implications for clinical practice

Oral antiviral maintenance treatment in patients with a history of frequent recurrences is of benefit. Daily maintenance treatment with oral antiviral agents reduces the frequency of recurrences, and improves the quality of life in comparison with placebo.

Valaciclovir appears to be somewhat better than famciclovir for suppressing genital herpes and associated shedding. Suppressive treatment with valaciclovir during the first year after acquisition of the infection, when recurrences are most frequent, increases significantly the patients' quality of life.

### Are antiviral interventions effective in preventing virus shedding in herpes simplex virus-seropositive asymptomatic immunocompetent adults?

#### Efficacy

Virus shedding occurring in HSV-seropositive asymptomatic individuals contributes to virus transmission. There are two RCTs, each with a crossover design after a washout period (one with valaciclovir, one with famciclovir), investigating virus shedding as primary outcome in asymptomatic HSV-seropositive subjects [57,58].

The first RCT compared the effect of valaciclovir 1 g/day for 60 days versus placebo on asymptomatic virus shedding in 73 immunocompetent, HSV-2-seropositive subjects without a history of symptomatic genital herpes infection.

Valaciclovir significantly reduced shedding during subclinical days compared with placebo (mean, 1.5% vs 5.1% of subclinical days ( $P < 0.001$ ), a 71% reduction). Eighty-four percent of subjects had no shedding while receiving valaciclovir versus 54% of subjects on placebo ( $P < 0.001$ ). Valaciclovir was not associated with any safety risk compared with placebo [57].

In another RCT, famciclovir (250 mg b.i.d. for 42 days) reduced genital and oral HSV shedding from 11.4% of days during the placebo period (42 days) to 4.7% of days during famciclovir therapy in HSV-seropositive asymptomatic persons without evidence of clinical disease. The reduction was greater in participants with a history of genital herpes (74%) than in those without such a history (30%). In multivariate analyses, famciclovir protected against total (clinical and subclinical) genital shedding among persons with a clinical history of genital herpes (RR, 0.23; 95% CI, 0.15–0.35;  $P < 0.001$ ). Among HSV-2 seropositive participants without a history of genital herpes, 60% had HSV detected in the genital area at least once during the study. Famciclovir therapy did not result in a statistically significant reduction in total HSV shedding in participants without a history of genital herpes [58].

Three separate but complementary open-label crossover studies of 4–7 weeks (separated by 1 week wash-out) compared (i) no medication with aciclovir 400 mg b.i.d. (standard-dose aciclovir), (ii) valaciclovir 500 mg/day (standard-dose valaciclovir) with aciclovir 800 mg three times daily (high-dose aciclovir), and (iii) standard-dose valaciclovir with valaciclovir 1 g three times per day (high-dose valaciclovir). Short bursts of subclinical genital HSV reactivation were frequent, even during high-dose antiherpes therapy. Of 113 participants randomized, 90 were eligible for analysis of the primary endpoint. Of 23 605 collected swabs, 1272 (5.4%) were HSV positive. The frequency of HSV shedding was significantly higher in the no medication group ( $n = 384$ , 18.1% of swabs) than in the standard-dose aciclovir group (25, 1.2%; incidence rate ratio [IRR], 0.05, 95% CI, 0.03–0.08). High-dose aciclovir was associated with less shedding than standard-dose valaciclovir: 198 (4.2%) versus 209 (4.5%); IRR 0.79; 95% CI, 0.63–1.00. Shedding

was less frequent in the high-dose valaciclovir group than in the standard-dose valaciclovir group: 164 (3.3%) versus 292 (5.8%); 0.54; 95% CI, 0.44–0.66. The number of episodes per person-year did not differ significantly for standard-dose valaciclovir (22.6) versus high-dose aciclovir (20.2;  $P = 0.54$ ), and standard-dose valaciclovir (14.9) versus high-dose valaciclovir (16.5;  $P = 0.34$ ), but did for no medication (28.7) and standard-dose aciclovir (10.0;  $P = 0.001$ ).

Median episode duration was longer for no medication than for standard-dose aciclovir (13 h vs 7 h;  $P = 0.01$ ) and for standard-dose valaciclovir than for high-dose valaciclovir (10 h vs 7 h;  $P = 0.03$ ), but did not differ significantly between standard-dose valaciclovir and high-dose aciclovir (8 h vs 8 h;  $P = 0.23$ ). Eighty percent of episodes were subclinical in all study groups. Except for a higher frequency of headaches with high-dose valaciclovir ( $n = 13$ , 30%) than with other regimens, all regimens were well tolerated [59].

#### Drawbacks

Treatments with aciclovir, valaciclovir, famciclovir, and placebo were all well tolerated. In contrast to the RCT with valaciclovir [57], famciclovir therapy did not result in a statistically significant reduction in total HSV shedding in participants without a history of genital herpes [58]. In recent open label crossover studies, despite high-dose antiviral treatment, short bursts of subclinical viral shedding were reported [59].

#### Comments

Asymptomatic viral shedding is considered to be the primary means of transmitting HSV to sexual partners. The results of these studies show differences between antiviral agents at the given dose to suppress viral shedding in asymptomatic subjects with no history of symptomatic genital herpes infection. Reduction of virus shedding may be achieved by chemoprophylaxis with valaciclovir even in asymptomatic subjects with no history of symptomatic genital herpes infection; however, short bursts still occur. Whether a reduced frequency and duration of viral shedding is sufficient to reduce the risk of transmission to an HSV-seronegative partner will require further studies.

Barrier methods are used for reduction of virus transmission. A systematic review based on six studies ( $n = 5384$  individuals who were HSV-2 negative at baseline) showed in a multivariate model a significant decrease in risk of HSV-2 acquisition with a 25% increase in condom use (HR, 0.93; 95% CI, 0.85–0.99;  $P = 0.01$ ) while the aggregate HR for 100% versus 0% condom use was 0.70 (95% CI, 0.40–0.94) [60].

In addition to approaches to control virus shedding in HSV-positive individuals, vaccines for HSV-negative subjects are being developed. Currently, several preclinical and clinical studies with different candidate vaccines (glycoprotein D-, peptide-, and DNA-based) and adjuvants are under investigation in HSV-negative as well as HSV-positive individuals to evaluate their benefit for new acquisition of infection as well as disease suppression with diverging results [61–65].

### Implications for clinical practice

To this point, no antiviral chemoprophylaxis provides complete protection from subclinical virus shedding and disease transmission. Barrier methods such as condoms are beneficial to reduce viral transmission. Vaccines are under development, but are not yet available in clinical practice.

## Are antiviral interventions effective in preventing maternal genital herpes simplex virus recurrences and neonatal infections?

### Efficacy

Among women with recurrent genital HSV, nearly 75% can expect at least one recurrence during pregnancy, and about 14% of women will have prodromal symptoms (early symptoms indicating the onset of an attack) or clinical recurrence at delivery [66]. Transmission of the virus from mother to fetus typically occurs by direct contact with the virus in the genital tract during delivery. The estimated incidence of neonatal herpes infection is broad, ranging from 5 to 80 per 100 000 live births [66]. To reduce neonatal transmission, it is currently recommended that a cesarean delivery be offered to all women with active genital lesions or prodromal symptoms at delivery [66].

A CSR on antiviral prophylaxis for preventing maternal genital HSV recurrence and neonatal infection [66] found seven RCTs (1249 participants) which met its inclusion criteria: five trials compared aciclovir (in doses of 400 mg p.o. t.i.d. or 200 mg p.o. four times daily) with placebo or no treatment. Two trials compared valaciclovir (500 mg p.o. b.i.d.) with placebo.

The  $I^2$  index indicates the degree of heterogeneity in the meta-analysis. Women who received antiviral prophylaxis (beginning from 36 weeks' gestation) were significantly less likely to have a symptomatic recurrence of genital herpes at delivery (RR, 0.28; 95% CI, 0.18–0.43,  $I^2 = 0\%$ ) and were also significantly less likely to have a cesarean delivery for genital herpes (RR, 0.30; 95% CI, 0.20–0.45,  $I^2 = 27.3\%$ ). They were significantly less likely to have HSV detected at delivery (RR, 0.14; 95% CI, 0.05–0.39,  $I^2 = 0\%$ ). The effect of antepartum antiviral prophylaxis on neonatal herpes could not be estimated. There were no cases of symptomatic neonatal herpes in the studies included in either the treatment or placebo groups [66].

### Drawbacks

A previous systematic review based on three RCTs dealing with the treatment of genital herpes in pregnant women found no evidence of adverse effects of aciclovir in the women or the newborns [67].

### Comments

Antiviral agents are not approved for the treatment of genital herpes in breastfeeding and pregnant women.

A recent CSR found the risk of neonatal herpes low in both treatment groups (antiviral and placebo). There is insufficient evidence to determine if antiviral prophylaxis for women with a history of genital herpes reduces the incidence of neonatal herpes. Antenatal antiviral prophylaxis reduces viral shedding and recurrences at delivery and reduces the need for cesarean delivery for symptomatic genital herpes. The risks, benefits, and alternatives to antenatal prophylaxis should be discussed individually with women who have a history and prophylaxis initiated in women who desire intervention [66].

## What are effective therapeutic interventions for the treatment of recurrent genital herpes simplex in immunocompetent adults?

### Efficacy

#### Aciclovir versus placebo

No systematic reviews were found. In one nonsystematic review ( $n = 650$  people) [44] in comparison with placebo oral aciclovir (200 mg five times per day or 800 mg twice per day, administered early at the first signs of recurrence for 5 days) reduced duration of

lesions (5 days with aciclovir vs 6 days with placebo) and the duration of viral shedding (1 day with aciclovir vs 2 days with placebo) [44].

In another RCT ( $n = 131$  individuals with more than three recurrences during the previous 12 months, followed at least until the next recurrence), aciclovir (800 mg three times per day for 2 days) significantly reduced the duration of episodes (median duration: 4 days with aciclovir vs 6 days with placebo;  $P < 0.001$ ), the duration of lesions (median duration: 4 days with aciclovir vs 6 days with placebo;  $P < 0.001$ ), and viral shedding (median duration: 25.0 h with aciclovir vs 58.5 h with placebo;  $P = 0.04$ ) [68]. The benefit was marked if the treatment was initiated early at the first signs of recurrence [69].

#### Valaciclovir versus placebo

One systematic review (based on one RCT, including 987 patients) [51,70] on patient-initiated treatment with oral valaciclovir (500 or 1000 mg twice per day for 5 days) versus placebo found a decreased duration of the lesion and accompanying discomfort (median duration: 4 days with valaciclovir vs 6 days with placebo; HR, 1.9; 95% CI, 1.6–2.3), a decreased duration of viral shedding (median duration: 2 days with valaciclovir vs 4 days with placebo; HR, 2.9; 95% CI, 2.1–3.9), and an increased rate of aborted recurrences in comparison with placebo (aborted recurrences: 31% with valaciclovir vs 21% with placebo; RR, 1.5; 95% CI, 1.1–1.9) [70]. No differences in the outcomes were noted between the two groups who received valaciclovir (500 mg b.i.d. vs 1000 mg b.i.d.) for 5 days. The lower dosage is therefore recommended.

#### Valaciclovir versus aciclovir/valaciclovir

One systematic review (based on one RCT;  $n = 739$ ) [71] on valaciclovir versus aciclovir showed that the two regimens (valaciclovir 500 mg b.i.d.) and aciclovir (200 mg five times per day) given for 5 days were equivalent with regard to healing time, symptom duration, and viral shedding [51].

No differences were observed between a 3-day and 5-day regimen with valaciclovir (500 mg twice per day;  $n = 531$  individuals with more than six recurrences per year) with regard to episode duration (4.7 days with the 3-day treatment vs 4.6 days with the 5-day treatment with valaciclovir; significance not reported) or aborted recurrences (27% with the 3-day treatment vs 21% with the 5-day treatment with valaciclovir (RR, 1; 95% CI, 0.92–1.65)) [72]. Initiating treatment within 6 h of the first symptoms was associated with a greater likelihood of aborted recurrences than initiation later than 6 h (odds ratio [OR], 1.93; 95% CI, 1.28–2.9) [72]. Another RCT (including 800 individuals with more than four recurrences per year) found concordant results with 3-day and 5-day treatment with valaciclovir (500 mg twice daily) [73].

#### Famciclovir versus placebo

One systematic review on famciclovir versus placebo (based on one RCT,  $n = 467$ ) [51,74] found that patient-initiated oral treatment with famciclovir (125 mg twice per day, 250 mg twice per day, or 500 mg twice per day for 5 days) led to significant reductions in the healing time (median 3.8 days for famciclovir recipients vs 4.8 days for placebo recipients), the duration of viral shedding (1.7 days with famciclovir vs 3.3 days with placebo), and the duration of symptoms (3.2 days with famciclovir vs 3.7 days with placebo;  $P$  values not reported) [74]. Famciclovir (125 mg twice daily) was effective, and higher doses did not confer any additional benefit.

In a recent RCT with a total of 299 patients with recurrent genital herpes (66% female, median age 37 years) treatment consisted either of 1-day famciclovir 1000 mg twice-daily ( $n=201$ ) or placebo ( $n = 98$ ). In the modified intent-to-treat population, there were similar outcomes for famciclovir and placebo in the estimated median time to healing of nonaborted genital herpes lesions (5.38 days for famciclovir and 4.79 days for placebo – median of treatment differences 0.26 days; 95% CI,  $-0.40$  to  $+0.98$ ;  $P = 0.416$ ) [75].

#### **Famciclovir versus aciclovir**

No significant differences were found in one RCT ( $n = 204$ ) between oral famciclovir and aciclovir with regard to the time to healing (mean: 5.1 days with famciclovir vs 5.4 days with aciclovir; mean difference,  $+0.3$  days; 95% CI,  $-0.3$  to  $+0.8$  days) [76].

#### **Novel drugs**

New drugs for the treatment of recurrent genital herpes have been investigated; for example, topical resiquimod (a Toll-like receptor 7/8 antagonist) and helicase–primase inhibitors (potent inhibitors of HSV-replication).

In an RCT with vehicle (39 subjects) versus resiquimod (0.01% gel two times per week over 3 weeks, 43 subjects), no difference between the groups was observed with respect to time to healing (median of 7.0 days (vehicle) versus median of 6.5 days (verum), respectively) and time to cessation of viral shedding (median of 7 days vs median of 5 days). Additionally, no significant effects on recurrence rates were observed in the phase III studies, resulting in the discontinuation of the development [77].

In contrast, 3-day or 1-day courses of ASP2151 (a helicase–primase inhibitor) appear to be effective and safe options for treatment of episodes of recurrent genital herpes demonstrated in an RCT that assessed the safety and efficacy of ASP2151 for episodic therapy of recurrent genital herpes. Participants self-initiated treatment with ASP2151 (100, 200, or 400 mg daily for 3 days), ASP2151 (1200 mg as a single dose), placebo for 3 days, or valaciclovir (500 mg twice daily for 3 days). Of 695 adults enrolled, 437 experienced a recurrence and received study drug. Median time for lesion healing was 139.8 h with placebo, 119.6 h with ASP2151 (100 mg; HR, 1.40;  $P = 0.065$ ), 106.2 with ASP2151 (200 mg; HR, 1.40;  $P = 0.081$ ), 115.9 with ASP2151 (400 mg; HR, 1.25;  $P = 0.25$ ), 102.1 with ASP2151 (1200 mg; HR, 1.72;  $P = 0.007$ ), and 113.9 with valaciclovir (500 mg twice daily; HR, 1.42;  $P = 0.077$ ), indicating improvement in all treatment groups except ASP2151 (400 mg). Incidence of treatment-emergent adverse events was similar across groups [78].

#### **Drawbacks**

Adverse effects (mostly headache and nausea) were rare and occurred at similar frequencies in all of the treatment groups (aciclovir, valaciclovir, famciclovir, placebo) [51].

#### **Comments**

Antiviral agents are not approved for the treatment of genital herpes in breastfeeding and pregnant women. One systematic review based on three RCTs dealing with the treatment of genital herpes in pregnant women found no evidence of adverse effects in either the women or the newborn [67].

#### **Implication for clinical practice**

Oral antiviral treatment (aciclovir, famciclovir, valaciclovir) initiated at first symptoms of recurrence (e.g., within 6 h) [72] is effective

with regard to total lesion clearance in the immunocompetent adult. They reduce the duration of lesions and viral shedding and increase the rate of aborted recurrences in comparison with placebo in individuals with recurrent genital herpes. Aciclovir, famciclovir, and valaciclovir are similarly effective in reducing symptom duration, lesion healing time, and viral shedding. The benefit was marked if treatment was initiated early, at the first signs of recurrence [69,72]. There is clinical evidence for effectiveness for a helicase–primase inhibitor from clinical studies; however, it is not available yet in clinical practice.

#### **Key points**

- For primary manifestations of oral/labial herpes (which may be severe), antiviral agents (such as aciclovir) are likely to be beneficial with regard to the mean time required for healing.
- Recurrences of herpes simplex labialis are common, but their frequency can be significantly reduced with prophylactic oral treatment with antiviral agents. The optimal timing and duration of treatment are uncertain.
- In reactivated herpes labialis, there is some evidence that topical penciclovir and aciclovir reduce the healing time.
- Oral aciclovir and valaciclovir (if taken early at the first symptoms of recurrence of labial herpes) may reduce the duration of lesions and pain.
- Oral antiviral treatment in the primary manifestation of genital herpes reduces the duration of lesions, symptoms, and viral shedding.
- Daily suppressive treatment with oral antiviral agents (aciclovir 400 mg twice per day, famciclovir 250 mg twice per day, or valaciclovir 500 mg once per day) reduces the frequency of recurrences. In patients with 10 or more recurrences per year, 1 g of valaciclovir once daily, 250 mg of valaciclovir twice daily, or 400 mg of aciclovir twice daily were more effective. Valaciclovir appears to be somewhat better than famciclovir in suppressing genital herpes and the associated shedding.
- Suppressive daily treatment with aciclovir in individuals with a history of recurrent herpes with aciclovir does not result in resistant HSV strains during or after the cessation of treatment in immunocompetent adults.
- Antiviral suppressive treatment can reduce virus shedding from asymptomatic subjects; however, short bursts of subclinical virus shedding occur despite high-dose antiviral treatment.
- There is insufficient evidence to determine if antiviral prophylaxis for women with a history of genital herpes reduces the incidence of neonatal herpes.
- Antenatal antiviral prophylaxis reduces viral shedding and recurrences at delivery and reduces the need for cesarean delivery for symptomatic genital herpes.
- In a clinically manifest recurrence of genital herpes, aciclovir, famciclovir, and valaciclovir are similarly effective in reducing symptom duration, lesion healing time, and viral shedding.
- No serious adverse events associated with topical antiviral agents (aciclovir, valaciclovir, or famciclovir) have been reported.
- Key research gaps in the field of herpes simplex include trials on interventions in primary oral/labial herpes simplex in the immunocompetent adult, trials to determine the maximal tolerable interval between the onset of disease and the start of treatment, and the optimal timing and duration of treatment to prevent recurrences.

# Leprosy

Saumya Panda

Department of Dermatology, KPC Medical College, Kolkata, India

## Background

### Clinical scenario

A 32-year-old man presented to the dermatology clinic with a rash. He had developed a single, raised, erythematous patch on his right upper arm 2 months previously, but had ignored it initially. Recently, he had noticed several new lesions developing on his right arm. The lesions were getting bigger and lighter in color, and he was unable to feel any sensation when he pressed on them. There were no other symptoms, and he was otherwise well. He was born in Madagascar and had moved to the UK 5 years previously. No one in his family had leprosy or tuberculosis. Examination revealed multiple well-demarcated, hypopigmented patches and plaques of different sizes on his right upper arm, with loss of pain and light touch sensation (Figure 49.1). There was no evidence of peripheral nerve thickening or loss of function. Histological examination of a skin smear from one of the lesions showed well-defined granuloma with epithelioid cells and a dense, lymphocytic infiltrate, but no acid-fast bacilli. The clinical and histological findings were consistent with a diagnosis of polar tuberculoid (TT) leprosy. When informed of his diagnosis, the patient mentioned that he had heard that leprosy could now be treated with a single dose of antibiotics. He had also read that some patients with leprosy also took steroids with their antibiotics to protect their nerves from permanent damage, and he wanted to be sure that this would be beneficial because he was concerned about the side effects of long-term steroids.

### Definition

Leprosy (from the Greek *lepros*, scaly, scabby, rough) is a chronic infectious granulomatous disease due to *Mycobacterium leprae* [1]. Most people exposed to the organism are able to mount an appropriate immune response and do not develop leprosy, and those who do usually present with single lesions, which often heal without treatment. In a small proportion, however, the lesion may progress to overt disease, the severity of which depends on the host's cell-mediated immune (CMI) response to *M. leprae*. Leprosy is classified according to the degree and type of host immune response as indeterminate (I), tuberculous pole (TT), borderline tuberculoid (BT), borderline (BB), borderline lepromatous (BL), and lepromatous (LL) pole [2].

For treatment purposes, patients are defined as paucibacillary (PB), with five or fewer skin lesions, or multibacillary (MB), with six or more skin lesions. PB leprosy includes TT and BT leprosy, while MB leprosy includes BB, BL, and LL patients [3]. Single-lesion leprosy is often defined separately as a subgroup of PB leprosy, as the treatment is different. In 2000, around 39% of leprosy patients worldwide were classified as MB, 52% as PB (two to five skin lesions), and 9% as having a single lesion [4].

Indeterminate leprosy (I) is considered to be the early stage of leprosy, which can self-heal and may be underdiagnosed. The lesions are vague, hypopigmented macules without definite anesthesia and/or nerve enlargement. In TT leprosy, however, the lesions may be hypopigmented or erythematous, with loss of pain, touch, hot and cold sensations, and lack of sweating due to sympathetic nerve damage. Skin smears often yield few or no bacilli, and the lesions may heal spontaneously. In borderline leprosy, the skin lesions become more numerous and larger, with less well-defined margins, and nerve damage becomes more prominent. In lepromatous leprosy, the overwhelming bacterial load and the limited host immune response results in generalized multisystem infection which, if left untreated, results in severe multiorgan damage. The skin lesions are larger, less well defined, symmetrical, more infiltrated, and often develop into plaques and nodules. The patient may present with extensive sensory and motor nerve damage. The nerves commonly affected are the ulnar and median (leading to claw hand), radial (wrist drop), common peroneal (foot drop), posterior tibial (claw toes), the fifth (corneal sensation) and seventh (facial palsy) cranial nerves, cutaneous sensory nerves especially near skin lesions, and auricular nerves. In advanced cases, the patients may present with loss of eyebrows and eyelashes, nasal cartilage damage with collapsed nose, epididymo-orchitis, and iritis, which may progress to blindness. Other forms of leprosy, such as primary neuritic leprosy without skin lesions, are also recognized and can be diagnosed by nerve biopsy [1].

Reactions in leprosy refer to episodes of acute inflammation of skin lesions, nerves or other body parts. Type I reactions (T1R), or reversal reactions, occur in borderline leprosy due to spontaneous fluctuations in the host CMI response to *M. leprae*, and can occur before, during, or after treatment, making it difficult to distinguish from relapse [5,6]. Patients present with swelling of the limbs and

**Figure 49.1** Multiple well-demarcated, hypopigmented patches and plaques of different sizes on the right upper arm in a 32-year-old patient.

face and the appearance of new skin lesions, which can ulcerate and scar. Neuritis, particularly involving nerves that are already enlarged, can occur either insidiously and painlessly or as a severe painful episode and may result in permanent nerve damage if not treated promptly. The lesions show infiltration of lymphocytes and monocytes, with elevated levels of interferon gamma. The risk of T1R is associated with facial lesions and more extensive disease [7]. The greatest risk of developing T1R is within the first year of starting treatment and is more severe at the tuberculoid end of the spectrum. With multidrug therapy (MDT), the risk of T1R is estimated at 7–20% in PB and 39–48% in MB patients [8]. It has been proposed that the use of more potent antileprosy drugs increases the risk of T1R by releasing large quantities of *M. leprae* antigens due to more effective killing of the organism, causing an exaggerated host immune response [9].

Erythema nodosum leprosum (ENL) describes the development of tender red papules and nodules on the skin and sometimes in the nerves and eyes of patients at the lepromatous end of the disease [5,10]. The lesions develop over a few hours and last a few days, and, unlike T1R, usually recur. They can coalesce to form large plaques and may even ulcerate. ENL occurs due to deposition of immune complexes formed by *M. leprae* antigens together with dysfunction of the host CMI response. Increased levels of tumor necrosis factor- $\alpha$  may have a role in the pathogenesis. The severity of ENL varies tremendously from asymptomatic episodes to gross prostration and even death. Systemic symptoms are often present and include fever, malaise, swelling of the hands and feet, and lymphadenitis. The joints, eyes, testes, liver, spleen, and kidneys may also be involved in severe cases. With clofazimine-containing multidrug regimens, ENL accounts for <1% of all reactions in many large-scale postsurveillance studies [11].

### Incidence/prevalence

The global prevalence of leprosy had declined steadily from its peak of 12 per 100 000 population in 1985 to less than one case per 100 000 by the end of 2000 [4]. Trends in new cases detected globally have also been falling since 2001. At the end of 2000, there were around 5.5 million cases registered for treatment globally, with 719 330 new cases detected that year [4]. Of the 122 countries in which leprosy was endemic in 1985, by the end of 2005 all but six countries (Brazil, Democratic Republic of the Congo, Madagascar, Mozambique, Nepal, and Tanzania) reported a prevalence of less than 1 per 10 000 [12]. In 2002, more than 620 000 new cases were detected, whereas in 2008 there were approximately 249 000 cases. In early 2009, the global prevalence of leprosy was approximately 213 000 cases [13]. It is estimated that over 14 million leprosy patients globally have been cured through MDT.

### Etiology

Progress in leprosy research has been slow, because it has not been possible to cultivate the organism in artificial media; most research is currently performed on the mouse footpad model [14]. The organism is considered to be of high infectivity but low pathogenicity and is rarely fatal. Humans are the main reservoir of infection, but the organism has been found in several primate species and armadillos. *M. leprae* is a rod-shaped, slightly curved, Gram-positive, obligate intracellular organism. The genome of *M. leprae* was published in 2000 and there are very few differences in genomes from *M. leprae* strains isolated from different geographical regions worldwide [15]. It is found mainly in clumps known as globi inside macrophages, and multiplies very slowly, with a generation time of around 12 days. *M. leprae* has a long and variable incubation period, ranging from 1 year to more than 20 years. The optimal temperature for growth is 27–30 °C, which explains its predilection for cooler parts of the human body. The mode of transmission of infection still remains speculative, but it is strongly suspected to involve the respiratory tract, since nasal secretions from infected individuals carry large numbers of the organisms.

Risk factors for leprosy remain poorly understood, but low socioeconomic status, overcrowding, nutritional status, and immune response all play an important role. Household contacts have a higher risk of developing leprosy, particularly if the index case has MB leprosy rather than PB leprosy, and children have a higher risk in comparison with adults [16]. Genetic factors may also influence susceptibility to leprosy and/or progression to overt disease. For example, allelic variants at the human homologue of the mouse natural resistance-associated macrophage protein 1 (Nrp1) gene have been found to be associated with susceptibility to tuberculosis and leprosy in humans [17]. The Nrp1 protein is an integral membrane protein expressed exclusively in the lysosomal compartment of monocytes and macrophages [18]. There is also a strong association between the HLA-DR2 allele and tuberculoid leprosy in ethnically diverse populations and between HLA-DQ1 and lepromatous leprosy [14,17,19]. Other studies have shown an increased risk of leprosy within certain families, high concordance rates among identical twins, and identification of genetic markers on chromosome 10 in linkage studies in south India [17].

### Prognosis and complications

Completion of the antileprosy treatment recommended by the World Health Organization (WHO) leads to cure in almost all cases, with an estimated relapse rate of less than 1% for both PB and MB leprosy [20]. Relapse is defined as reappearance of the

disease, gradual worsening of existing lesions, appearance of new skin lesions, thickened, tender nerves, or muscle paralysis after successful completion of the appropriate treatment and can occur many years after treatment completion. Relapse is mainly diagnosed clinically, although some cases may be identified by routine skin smear tests during posttreatment surveillance, and can be difficult to distinguish from late reactions. A delay in detecting relapse, which often occurs because patients falsely assume they have been cured [21], can lead to further nerve damage and deformities.

However, the main complication of leprosy is the severe disfigurement and deformity that occurs and progresses even after treatment completion. The International Classification of Impairment, Disease and Handicap emphasizes that deformities, defined as alteration in the form, shape, or appearance of parts of the body, result in impairment and not disability [22]. Disability is defined as any restriction or lack of ability to perform in the manner or within the range considered normal for a human being as a result of impairment. The risk of disability in leprosy is complex and associated with age, sex, occupation, classification, and duration of disease, development of reactions, site of lesions, method of case detection, geographic and socio-economic factors, treatment type, educational attainment, and ethnicity [23]. Early identification of the disease is very critical for effective control and disability limitation. A recent study in Nigeria, which used the incidence of disability grade 2 among the new cases as a comparator, found that complementing routine practice with household contact examination to be the most cost-effective approach to identify new leprosy cases [24].

Deformities in leprosy result from *M. leprae* infection, reactions, and relapse, all of which can cause irreversible nerve damage. Neurophysiological changes indicating axonal and demyelinating processes during both T1R and T2R were detected during a clinical trial of steroid treatment effectiveness [25]. The subsequent loss of sensory, motor, and/or autonomic modalities to peripheral limbs often leads to trauma and ulceration of areas supplied by the nerves, eventually leading to gross deformities and even loss of the limb. Psychosocial disabilities are also common and arise from the chronic nature of the disease, the unsightly mutilations that occur, and the stigma associated with leprosy. Thus, loss of confidence, feelings of inadequacy, low self-esteem, anxiety, and frank depression are common among leprosy patients, who are also more likely to be unmarried, divorced, unemployed, and homeless [21]. Another group among whom the prevalence of dementia and depression is particularly high consists of the long-term institutionalized older leprosy patients, as was found in a study conducted in Taiwan [26].

In 1969, the WHO redefined its five-point classification of disability to three grades to facilitate its use by field workers worldwide, and simplified it further in 1988 to two grades only (Table 49.1) [23], with the primary aim of collecting data regarding disability for administrative purposes. In 1995, the global prevalence of grade 2 disability among leprosy patients was estimated at 1–2 million, compared with 3.5 million in 1975 and 3.9 million in 1966. By 2000, of almost 700 000 new cases with information on disability status, only 4% had grade 2 disabilities at presentation [4].

## Diagnostic tests

The diagnosis of leprosy is based principally on the clinical features and can be confirmed by skin smears or biopsy. Leprosy should be suspected in any patient presenting with an anesthetized skin lesion, with or without nerve involvement. Sensory loss to pinprick

and/or light touch is a typical feature of leprosy [17]. The WHO defines a case of leprosy as involving one or more of the following features in anyone who has not completed antileprosy treatment:

- hypopigmented or reddish skin lesion(s) with sensory loss;
- involvement of the peripheral nerves, with thickening or loss of sensation in the area supplied by the nerve;
- skin smear positive for acid-fast bacilli [27].

When performed properly, skin smears can help confirm the diagnosis of leprosy, aid correct classification, monitor treatment progress, and diagnose relapse. The bacterial load can be estimated and expressed using the logarithmic Ridley scale or bacterial index (BI; grades 0–6) based on the number of bacilli seen in an average microscopic field using an oil immersion lens [28]. The morphological index (MI) can be used to determine the percentage of live organisms – a score of zero means that patient is noninfectious.

A biopsy of the skin lesion may help confirm the diagnosis, improve research, and allow culture of *M. leprae* in mouse footpads. However, the sensitivity is poor, because biopsies can yield negative results despite obvious clinical signs. Leprosy lesions are characterized by the formation of granulomas, which vary from the epithelioid type at the tuberculous end to the “foamy” cell type (macrophages filled with *M. leprae*) at the lepromatous end. Immunohistopathological staining for *M. leprae* antigens, such as phenolic glycolipid-1 (PGL-1), have been shown to be very specific, but are still in the developmental stage [29].

The lepromin skin test, which involves injecting inactivated *M. leprae* antigens under the skin, can be used to aid disease classification and predict the type of disease a person is likely to develop, as it measures the host's CMI response against *M. leprae* antigens [17]. The site of injection is examined at 3 days and again at 3–4 weeks after injection for reaction induration. A positive test would suggest the development of leprosy at the tuberculoid end of the spectrum, while a negative test would favor lepromatous leprosy.

Other diagnostic tests have been developed and are currently mainly used for research and epidemiological studies, but many show promise for future use in rapid diagnosis, monitoring therapeutic responses, and early diagnosis of relapse. Serological tests include measurement of anti-PGL-1 antibodies in blood or urine. Although these antibodies are often absent at the tuberculoid end of the spectrum, they may play an important role in early detection of relapse in MB patients and in detection of subclinical infection, because they can be present before the onset of clinical symptoms [14]. A systematic review incorporating 26 studies has affirmed that with a simple and robust technique the use of PGL-1 serology is viable [30]. Detection of *M. leprae* in tissues, using several polymerase chain reaction methods and probes targeting stretches of *M. leprae* DNA or ribosomal RNA, has also been developed and is

**Table 49.1** The 1988 World Health Organization grading of disability

Grade	Hands and feet	Eyes
0	No anesthesia, no visible deformity or damage	No eye problems due to leprosy; no evidence of visual loss
1	Anesthesia present, but no visible deformity or damage	Eye problems due to leprosy present, but vision not severely affected as a result (vision 6/60 or better; can count fingers at 6 m)
2	Visible deformity or damage present	Severe visual impairment (vision worse than 6/60; unable to count fingers at 6 m)

Source: WHO, 1988 [23]. Reproduced with permission of WHO.

potentially both sensitive and specific, although relatively expensive and impractical for use in the field [31].

### Aims of treatment

Treatment is aimed at:

- eliminating *M. leprae*;
- reducing reactions and relapse;
- preventing disabilities.

### Relevant outcomes

- Clinical outcomes:
  - percentage of patients with marked clinical improvement;
  - percentage of patients completely cured;
  - percentage of patients with treatment failure
  - percentage of patients with type I reaction;
  - percentage of patients with type II reaction;
  - percentage of patients relapsed.
- Bactericidal activity:
  - bacterial index (BI);
  - morphological index (MI);
  - mouse footpad test for *M. leprae*.
- Histopathological assessment:
  - percentage of patients with inactive leprosy.

### Methods of search

Randomized controlled trials (RCTs) dating back to 1966 were located by searching Medline, Embase, the Scientific Citation Index, and the Cochrane Library. The main search terms were RCT(s) or clinical trial(s); leprosy or lepra reactions or ENL. A Medical Subject Headings (MeSH) search was conducted if possible; otherwise a keyword search was used. References in original and review articles were reviewed and any RCTs missed from the electronic search were included. Only English-language trials were assessed.

### Questions

Because almost all RCTs on leprosy have been performed in endemic areas, care must be taken in extrapolating the results to developed countries with a low risk for leprosy.

### Is multidrug therapy more effective than monotherapy in terms of clinical outcomes and bactericidal activity?

#### Efficacy

No systematic reviews were found. Five RCTs were identified. Dietrich *et al.* compared two MDT therapy regimens with dapsone monotherapy [32]. A total of 307 patients with lepromatous leprosy and borderline lepromatous leprosy were randomly allocated to dapsone monotherapy, dapsone–rifampin, or dapsone–prothionamide–isoniazid–rifampin. The patients were treated once daily for 3 years and followed up for 5 years. Clinical improvement, regression of the disease, and bactericidal activity were measured. The results showed that dapsone monotherapy was associated with the same frequency of clinical improvement as both combinations at the end of the 5-year observation period, but with slightly slower regression. The trial did not find any statistical difference in the clearance of bacteria between the monotherapy and either combination. There was no difference in the type or frequency of reactions, but three relapses were observed with dapsone monotherapy. Ji *et al.* compared the efficacy of the combination of ofloxacin

400 mg, dapsone 100 mg, and clofazimine 300 mg daily with ofloxacin (400 mg and 800 mg) daily alone for 56 days [33]. The results showed that all of the treatment regimens were associated with remarkable clinical improvements. Marked improvements were seen in five of eight, six of eight, and six of eight cases for the combination, ofloxacin 400 mg, and ofloxacin 800 mg, respectively. The mouse footpad test showed that all three treatments led to more than 99% *M. leprae* organism clearance. There were no statistically significant differences in clinical improvement and bactericidal activity (BI and MI) between the groups. However, three ENL reactions were seen in the combination group.

Four RCTs were undertaken to compare the risk of reaction between MDT and monotherapy. Table 49.2 summarizes the results for relative risk between the two treatments [9,33–35].

Only one trial showed a significantly lower risk of type I reaction with MDT in PB leprosy [9]. The relative risk between MDT and the monotherapy was 0.12 (95% confidence interval [CI], 0.04–0.35). The number needed to harm was –6 (95% CI, –4 to –16), indicating that one in six patients would be protected from type I reactions when treated with MDT in comparison with the multiple-dose regimen of rifampicin monotherapy. Nevertheless, single-dose rifampicin (SDR) monotherapy had no more risk of the reaction than MDT.

### Drawbacks

Apart from reaction and relapse, none of the trials reported adverse drug events separately for the various treatment regimens, providing no comparative values for harms with these treatments.

### Comment

Except for two studies [9,32], all of the other trials are underpowered. Although Dietrich *et al.* indicated a rapid regression of the disease with MDT at the early stage of the treatment (6 months), there was no more benefit at the end point of 5 years with this regimen [32]. MDT was superior to multidose monotherapy in reducing type I reactions in PB leprosy [9]. However, the evidence is sparse, and the benefit of MDT disappears in comparison with SDR. As the trials differ with regard to the treatment regimens used and their duration, pooling is not possible. In addition, there are no RCTs comparing the standard WHO-MDT with dapsone monotherapy. Whether MDT is more beneficial than monotherapy has yet to be established.

### Implications for clinical practice

MDT may be useful to speed up clinical improvement and reduce type I reactions.

### Is single-dose multidrug therapy – such as 600 mg rifampicin, 400 mg ofloxacin and 100 mg minocycline – as effective as the standard World Health Organization multidrug therapy for paucibacillary leprosy in clinical outcomes?

#### Efficacy

No systematic reviews were identified. Three randomized controlled trials compared single-dose 600 mg rifampicin, 400 mg ofloxacin and 100 mg minocycline (ROM) with WHO-MDT in the treatment of PB leprosy, one for a single lesion, another for two or three lesions, and yet another for two to five skin lesions [36–38]. All the trials were double blinded. The patients were followed up for 18 months in two trials, and for 36–48 months (1082/1526) in the other. The percentages of patients with marked clinical improve-

ment were slightly in favor of the WHO-MDT for a single lesion of PB leprosy. The rate ratio was 0.90, with a 95% CI of 0.82–0.995 ( $P < 0.05$ ) (Table 49.3) [36,37,39].

The number needed to treat was –18 (95% CI, –9 to –367), indicating that 1 in 18 patients will obtain marked clinical improvement when treated with WHO-MDT in comparison with single-dose ROM. However, this benefit was not seen in multiple lesions of PB leprosy (Table 49.3).

Similar results were obtained for the percentage of patients with complete cure (lesion disappearance), with the single-dose ROM regimen showing a lower rate of complete cures than the WHO-MDT regimen in patients with single-lesion PB leprosy

(relative risk [RR], 0.86; 95% CI, 0.77–0.95;  $P < 0.01$ ). However, there were no differences in the percentage of patients with treatment failure (no clinical improvement) between the two regimens in patients with single and multiple lesions. The pooled relative risk in the first two RCTs was 0.98, with a 95% CI of 0.41–2.34 ( $P > 0.05$ ). In the third trial, which took into account patients with two to five skin lesions showing complete clearance, the result at 36 months of posttreatment follow-up was similar in both the arms (72% in ROM compared with 72.1% in WHO-PB-MDT; mid- $P$  exact 0.95) [38]. At the end of 48 months of posttreatment follow-up there was a further increase in complete clearance of lesions with the proportion remaining similar (75% vs 79%; ROM vs WHO-PB-MDT;

mid-*P* exact 0.25). The mean clinical scores were also declining in a similar way. The mean clinical scores (SD) at the baseline were 13.6 (5.4) versus 13.8 (5.3) compared with 2.2 (3.5) versus 2.1 (3.4) at the end of 48 months in ROM and WHO-PB-MDT arms, respectively. However, there was a higher relapse rate among those treated with ROM (3.8%) as compared with WHO-PB-MDT (1.2%). The difference was statistically highly significant at 36 months of follow-up ( $P = 0.001$ ) (Table 49.3). At 48 months, the difference was not that significant ( $P = 0.07$ ). It was observed that 20 of the 29 relapses with ROM occurred within 18 months and the remaining nine within 36 months of completion of treatment. In the additional 12 months of follow-up, no relapses occurred in 1082 patients [38].

### Drawbacks

Gastrointestinal and allergic adverse drug events were assessed in all trials. There were no statistically significant differences between the single-dose regimen and the WHO-MDT regimen. The pooled relative risk in the first two trials was 0.48 (95% CI, 0.15–1.56). In the trial, 10 suspected adverse drug reactions were reported. Eight of 10 among these were observed in the WHO-PB-MDT arm. Though statistically not significant, the occurrence of more drug reactions in the WHO-PB-MDT arm was of clinical significance [38].

Reaction and neuritis were also compared, and nonstatistical differences were obtained. The relative risks in the first two trials for these between the single-dose treatment and WHO-MDT were 2.66 (95% CI, 0.78–9.13) and 3.02 (95% CI, 0.31–28.97), respectively. In the third trial, one T1R in each of the arms was observed.

### Comment

The three RCTs that compared single-dose ROM with WHO-MDT were generally of good quality. The first and the third trials were well powered, with drop-out rates of 6% and 11%, respectively. The results show that clinical improvement (the percentage of patients with marked improvement or complete cure) is slightly in favor of the WHO-MDT regimen in the RCT with a single lesion of PB leprosy, but not with two or three lesions. There was hardly any difference of efficacy in the larger RCT with PB leprosy having two to five lesions. There are no differences in the other outcomes, such as treatment failure and reaction. Regarding side effects, there is no statistical difference between ROM and WHO-PB-MDT, but the latter demonstrated the occurrence of adverse drug reactions that would be clinically significant. The RCT with the longest follow-up indicated that ROM had a significantly higher relapse rate, the relapses having been essentially observed in the first 2 years of follow-up.

### Implications for clinical practice

The clinical efficacy of single-dose ROM in PB leprosy with up to five skin lesions is comparable to WHO-PB-MDT in clearing the lesions. However, ROM has a significantly greater tendency of causing relapse. If single-dose ROM is to be incorporated as a standard treatment regimen, active surveillance of the patients for at least 2 years has to be mandatory. This would require training of treating physicians in clinical evaluation of leprosy patients to detect reactions, relapses, and treatment failures, and it also brings in the question of patient compliance beyond the period of active treatment. Such close surveillance would thus be beyond the logistic capabilities of most leprosy programs. Therefore, single-dose ROM is not practically implementable at present, keeping the field

conditions in consideration. Minor modifications in ROM do not help in improving the clinical outcome, as an RCT assessing the effect of adding clarithromycin to ROM in the treatment of single-lesion PB leprosy found that the addition did not significantly improve the efficacy as measured in terms of cure rates and relapse rates [40].

For the patient in the clinical scenario described at the beginning of this chapter, single-dose ROM would not be suitable if he had more than five lesions at presentation. Even if the patient had up to five skin lesions, he would have to undertake submitting himself to close active surveillance for a period of at least 2 years if he wanted to be treated by single-dose ROM.

## Is 6 months of uniform multidrug therapy as safe and effective as 12 months of World Health Organization multidrug therapy in multibacillary leprosy?

### Efficacy

No systemic reviews were found. Two trials were identified. One was an open comparative trial between WHO-MDT (12 months) and uniform MDT (U-MDT, 6 months) in all types of leprosy over 24 months of observation [41]. Out of the 127 patients included, 64 patients (MB leprosy: 32/64) could be followed up regularly, and 44 of them were also assessed at 24 months of the study. The MB WHO-MDT and U-MDT groups were comprised of 22 and 10 patients, respectively. As per clinical improvement grading, good responses in the WHO-MDT group were 36%, 45%, and 77% at 12 months, 18 months, and 24 months of study, respectively, whereas the U-MDT group did not have a single good response at 12 and 18 months, with the poor responses being 50%, 67%, and 75% at 12 months, 18 months, and 24 months, respectively. These differences between the groups were statistically significant at all time intervals (at 12 months,  $P = 0.0465$ ; at 18 months,  $P = 0.0014$ ; at 24 months,  $P = 0.0064$ ). Histopathological assessment showed a higher percentage of good responses in the WHO-MDT group (100%) compared with U-MDT (50%) at 18 months.

The other trial was an open-label RCT comparing WHO-MDT with U-MDT, the primary outcome measure being the association of the treatment duration with the frequency of reactions among MB patients [42]. The reaction frequency in time was analyzed using the Kaplan–Meier survival function comparing the two groups and stratified by  $BI < 3$  and  $BI \geq 3$ . Those on UMDT (120/316) had more reactions than those on WHO-MDT (90/280). The biggest difference in the free-of-reaction proportion as a function of time was found around 1 year (difference of 11.9% at 1.15 years). The gap closed down around 2 years. Those with  $BI \geq 3$  had a higher frequency of first reaction than those with  $BI < 3$  throughout the observation time. The incidence of recurrent reaction presented a positive association with  $BI \geq 3$  and with U-MDT. The interaction term showed statistical significance, meaning that the simultaneous influence of U-MDT and  $BI \geq 3$  was less than the sum of the effect of each of these variables. There was a very strong association between the occurrence of T2R and  $BI \geq 3$ : an odds ratio of 11. Surprisingly, the difference in reaction frequency between treatment groups was more relevant among those with a low BI than those with a high BI.

### Drawbacks

Other than T1R and T2R, dapsone syndrome ( $n = 1$ ), acute generalized exanthematous pustulosis to dapsone ( $n = 1$ ), and clofazimine pigmentation ( $n = 11$ ) were recorded in one trial [41].

## Comment

The first study was a quasi-randomized (alternate allocation) open study with inadequate statistical power. The histopathological comparison should be treated with particular caution as the number of biopsy samples was so small that statistical methods could not be applied. Still, it has been included here because of the paucity of direct comparative studies between 6-month and 12-month MDT. The main problem in evaluating any new treatment regimen in leprosy is that there are no good and reliable data available for the current 12-month regimen. No RCT supports the reduction of treatment duration to 12 months for MB patients [42]. Only one multicentric, initially double-blinded clinical trial in 189 MB leprosy cases exist where, after 12 years of initiation of treatment, not a single case of long-term relapse was found in the 24-month MDT group, and a relapse rate of 3% (1/36) was recorded in the 12-month WHO-MDT group [43]. A hospital-based retrospective data analysis carried out in eastern India a decade after the commencement of the 12-month WHO-MDT showed that significant transmission of leprosy has been going on in the community, as evidenced by a significantly higher proportion of PB disease compared with MB leprosy [44].

In this context, the observation that MB patients on U-MDT showed a significantly poor response at all periods of clinical assessment at 12, 18, and 24 months compared with the patients on WHO-MDT [41] is relevant. Similarly relevant is the finding of the RCT [42] that shows that although the risk of first reaction converges 2 years after the beginning of treatment, the Kaplan–Meier curves separate when the U-MDT ends and the WHO-MDT group patients are still taking their drugs. It is also relevant that the same trial found that the incidence of recurrent reaction was associated with treatment duration and initial BI.

## Implications for clinical practice

There is no evidence that 6-month U-MDT is as efficacious or safe as the current 12-month WHO-MDT with regard to MB leprosy. Hence, there is no rationale to implement 6-month U-MDT only on operational grounds.

## Does a daily 4-week ofloxacin–rifampicin regimen have similar long-term relapse rates as the standard World Health Organization multidrug therapy in paucibacillary and multibacillary leprosy?

### Efficacy

No systematic review was identified. Three double-blind RCTs were identified [43,45,46]. Two of them compared the long-term relapse rates of ofloxacin–rifampicin with the WHO-MDT in MB leprosy [43,45] and one [46] compared the same in PB leprosy. The RCTs were too heterogeneous to combine in a statistical analysis.

In one of the multicenter trials [43], carried out in the Philippines, the relapse rates in 189 MB leprosy patients were treated with four different regimens and were followed up for as many as 12 years after the initiation of treatment. Treatment regimens included 1-year WHO-MDT, 2-year WHO-MDT, 1-month daily ofloxacin–rifampicin, and 1-year WHO-MDT plus initial 1-month daily ofloxacin–rifampicin. Relapse rates after 9 and 12 years from the initiation of therapy in the three regimens that included WHO-MDT were 0–3%, whereas relapses occurred in those treated with the 1-month regimen alone at a significantly greater rate ( $P < 0.05$ ): 11% at 9 years and 25% at 12 years. Relapses occurred late, beginning at 5 years after the initiation of therapy, and were confined to

those patients who were histopathologically borderline lepromatous and polar lepromatous having a high bacterial burden. No difference in the relapse rates (3% each at 12 years) for the two regimens employing WHO-MDT for 1 year (alone and with initial 1 month of daily ofloxacin–rifampicin) means there is no additional benefit of adding 1-month daily ofloxacin–rifampicin to the existing WHO-MDT regimen in MB leprosy. Though there was no statistically significant difference with 1-year WHO-MDT, it is noteworthy that only the 2-year WHO-MDT study population showed zero relapse at 2 years.

In another multicentric double-blind RCT with 198 MB patients [45], done in Brazil, employing four identical regimens with a shorter follow-up period (7 years after release from treatment), relapse occurred in those treated with 1-month regimen alone at a significantly higher rate ( $P < 0.001$ ): 38.8% (19/49; 95% CI, 25.5–53.3). In the other three regimens that included WHO-MDT it ranged from 0 to 5%. (in the 2-year WHO-MDT, there was zero relapse ( $n = 24$ ); in the 1-year WHO-MDT, relapse rate was 4.3% (2/46; 95% CI, 0.8–16.0); and in the group treated with 1-year WHO-MDT plus 1-month initial daily ofloxacin–rifampicin the relapse rate was 5% (2/40; 95% CI, 0.3–18.2). All relapses occurred in patients who were initially BL or LL and had a baseline average BI of  $4.2 \pm 0.84$ . These results indicate close correlation between relapse and high initial BI. These results, in spite of a much shorter follow-up period compared with the Filipino study, mirror those results demonstrating that 1 month of rifampicin and ofloxacin daily was insufficient in the treatment of MB leprosy.

In another double-blind, placebo-controlled, randomized trial carried out in the Philippines [46], 124 patients of PB leprosy were enrolled. Of them, 66 received the standard 6-month WHO-MDT regimen, whereas 58 received 28 daily supervised doses of rifampicin 600 mg + ofloxacin 400 mg, plus 5 months of placebo. Patients enrolled in the WHO-MDT group had a mean follow-up of 11.3 years with two late relapses at 8 and 12 years. Among those enrolled in the ofloxacin group, a mean follow-up of 10.8 years showed one early relapse at 3 years after treatment completion. The results show that the 4-week ofloxacin regimen was as safe and effective as the 6-month WHO-MDT regimen in PB leprosy.

### Drawbacks

The trial with PB leprosy [46] recorded mild reversal reaction in 4.5% (3/66) in the WHO-MDT group and 12% (7/58) reversal reactions in the rifampicin–ofloxacin group, two of which were considered to be moderate to severe. One patient in the ofloxacin group developed grade 2 deformity after treatment. One patient in the same group complained of occasional epigastric pain (not requiring cessation of treatment) towards the later part of treatment. In the Brazil trial on MB leprosy [45], among 183 patients who completed the course of treatment, three patients were decoded due to severe side-effects, including one on ofloxacin–rifampicin. Incidence of reversal reactions, if any, was not mentioned. There was no mention of any adverse effects in one study [43]. Overall, the incidence of side-effects was low, except that of reversal reactions in PB leprosy patients on ofloxacin–rifampicin.

### Comment

The three RCTs were well designed. The two trials on MB leprosy found that the relapse rate on the 4-week daily regimen of ofloxacin–rifampicin was significantly higher than three other regimens that included 1-year WHO-MDT, 1-year WHO-MDT plus 1-month initial daily ofloxacin–rifampicin, and 2-year WHO-MDT. It was

also found that the addition of 1 month of daily ofloxacin–rifampicin to 1-year WHO-MDT did not increase in its efficacy, as evidenced by the relapse rate – while in one trial the relapse rate of the combined regimen was, in fact, higher than the WHO-MDT alone (5% vs 4.3%), but not significantly so, in the other trial the rate was exactly the same (3%).

As suggested earlier [47], a short incubation period for relapse could have correlation with drug resistance. The short incubation period (2.5 years follow-up) for relapse in the case of ofloxacin resistance seems to suggest the possibility of relapse due to drug resistance [45].

Another important observation is the zero relapse with 2-year MDT, though this could be due to the small cohorts (9 and 24, respectively at the end of 12 years and 7 years) and insufficient follow-up period.

In PB leprosy, the 4-week ofloxacin regimen was found to be as safe and effective as the PB WHO-MDT. However, the early relapse in the ofloxacin regimen gives rise to the possibility that the short regimen might be inadequate in a small proportion of PB cases with a higher bacillary load. This possibility renders the applicability of the ofloxacin regimen even in PB leprosy doubtful, as it is very difficult to determine the treatment in the field on the basis of bacillary load.

### Implications for clinical practice

A 4-week ofloxacin–rifampicin daily regimen is not suitable for treating MB leprosy on account of a high relapse rate in comparison with the current 1-year WHO-MDT. The same regimen was found to be as safe and effective as the 6-month PB WHO-MDT. But the occurrence of early relapse in cases of higher bacillary load in PB leprosy with ofloxacin means that it is difficult to apply this regimen in the field, particularly in the endemic areas in the developing world.

### Is there any efficacious treatment for erythema nodosum leprosum?

#### Efficacy

One systematic review was identified [48]. It included 13 randomized trials with a total of 445 participants. The interventions included were: betamethasone (single trial), thalidomide (five trials), pentoxifylline (single trial), clofazimine (three trials), indomethacin (two trials), and levamisole (single trial). Treatment with thalidomide showed a significant remission of skin lesions compared with acetylsalicylic acid (aspirin) (RR, 2.43; 95% CI, 1.28–4.59 – single trial, 92 participants). Clofazimine treatment was superior to prednisolone (more treatment successes; RR, 3.67; 95% CI, 1.36–9.91 – single trial, 24 participants), and thalidomide (fewer recurrences; RR, 0.08; 95% CI, 0.01–0.06 – single trial, 72 participants). There was no significant benefit for intravenous betamethasone compared with dextrose (single trial, 10 participants), pentoxifylline compared with thalidomide (single trial, 44 participants), indomethacin compared with prednisolone, aspirin, or chloroquine (two trials, 80 participants), or levamisole compared with placebo (single trial, 12 participants).

#### Drawbacks

Twenty cases of drowsiness, eight cases of dizziness, and seven cases of nausea were seen with thalidomide treatment among 85 patients, whereas none was found with placebo [49]. Mild to moderate adverse events were significantly lower in participants taking 100 mg thalidomide compared with 300 mg thalidomide daily (RR,

0.46; 95% CI, 0.23–0.93;  $n = 22$ ) [50]. Significantly more minor adverse events were reported in participants taking clofazimine compared with prednisolone (RR, 0.46; 95% CI 1.10–3.35;  $n = 24$ ) [51].

### Comment

The quality of the trials was generally poor in relation to the Consolidated Standards of Reporting Trials (CONSORT) statement [52]. No results could be pooled owing to the interventions being so heterogeneous. There was some benefit for thalidomide and clofazimine, but generally there was no clear evidence of benefit for interventions in the management of ENL. However, this does not mean that they do not work, because the trials were small and poorly reported. However, it must be emphasized that because of its well-known teratogenicity, thalidomide should be given only to males and postmenopausal females. Women of childbearing age should never be given thalidomide. Thalidomide is also known to be associated with irreversible nerve damage. It must, therefore, be administered under the strictest possible supervision.

It is noteworthy that the results of a double-blind trial strongly support the beneficial effects of pentoxifylline in treating ENL [53]. Clinical evaluations carried out at the end of 30 days of treatment clearly indicated that the overall response to thalidomide was significantly better than the response to pentoxifylline ( $P = 0.02$ ;  $n = 44$ ). However, the results suggested that pentoxifylline could represent a good alternative treatment for ENL patients for whom thalidomide is contraindicated.

A randomized comparative trial was published recently comparing thalidomide and prednisolone in moderate to severe ENL [54]. Sixty adult MB patients with a histologically confirmed diagnosis of moderate to severe ENL were randomly allocated to two groups with similar baseline characteristics. Thalidomide had a very significantly superior efficacy across all clinical outcome parameters; namely, time taken for resolution of cutaneous lesions as well as constitutional symptoms, mean period of remission, and number of relapses ( $P < 0.0001$ ). Adverse events were more commonly noted in the prednisolone group. However, two patients had to be taken out of the thalidomide group, one on account of leukocytoclastic vasculitis and the other because of gastrointestinal symptoms.

### Implications for clinical practice

Thalidomide may be useful for improving the clinical symptoms of ENL, but owing to its well-known teratogenicity and neurotoxicity, care must be taken when it is being used for ENL. Current evidence would support the use of thalidomide in moderate to severe ENL, and clofazimine in mild ENL. Pentoxifylline can be employed where thalidomide is contraindicated. There is no ground for preferring the use of corticosteroids in ENL with respect to the above-mentioned interventions.

### In patients with leprosy, does steroid treatment improve nerve function impairment?

#### Efficacy

One systematic review was identified [55]. Three RCTs involving 513 participants were included. The interventions and outcomes were too heterogeneous to be entered in a meta-analysis. Risk of bias was generally low in the three RCTs. None of the trials found a significant difference in improved nerve function between treatment and control groups 12 months after start of treatment. Two trials compared prednisolone with placebo. One trial with 84 par-

ticipants treated mild sensory impairment of less than 6 months' duration, and the other trial, which had 95 participants, treated NFI of 6–24 months' duration. After 12 months of starting treatment, there was no significant difference in nerve function improvement between subjects treated with prednisolone or with placebo. The third trial compared three corticosteroid regimens for severe T1R in 334 participants. The results showed significant benefit of a 5-month steroid regimen over a 3-month regimen. After 12 months, a significantly higher proportion of individuals on the 3-month course of prednisolone required extra corticosteroids, a measure of poor outcome, compared with the groups with a high-dose and low-dose regimen of 5 months' duration. The main objective of this trial was to investigate failure to respond to the given corticosteroid regimen. Unfortunately, the effect of different corticosteroid regimens on nerve function improvement was not evaluated, which makes this trial unsuitable for comparison with other included trials.

### Drawbacks

The adverse effects of long-term steroid use are well known and include fluid retention, weight gain, redistribution of body fat, osteoporosis, muscle wasting, thinning of skin, and psychological effects, including irritability and depression. However, the occurrence of adverse effects was not significantly higher in the corticosteroid group compared with the placebo group (RR, 1.47; 95% CI, 0.35–6.24) [55]. While only two trials, which were limited in size and power, reported adverse effects, the evidence was inconclusive. Diabetes and peptic or infected ulcer were sometimes reported as serious adverse events in the placebo-controlled trials, but not significantly more often in the corticosteroid than in the placebo groups. Therefore, the occurrence of these major adverse events should not be considered a contraindication for corticosteroid treatment.

### Comment

Corticosteroids are used for treating acute nerve damage in leprosy, but evidence from two RCTs, treating either long-standing or mild NFI, did not show a significant long-term effect. A third trial showed significant benefit of a 5-month steroid regimen over a 3-month regimen. Standard corticosteroid regimens are not significantly more harmful than placebo treatment, despite known adverse effects of corticosteroids.

A more recent RCT of oral steroids for ulnar neuropathy in 21 patients with T1R ( $n = 12$ ) and T2R ( $n = 9$ ) showed that during the first month higher doses of steroids produced better results in both reactions, but earlier treatment with a lower dose was as effective [56]. The outcome was based on clinical score as well as neurophysiological evaluation. The results from this cohort of leprosy patients in reactional states are very relevant because it is known that while peripheral nerve damage can be demonstrated in almost all the patients with leprosy, a reaction episode significantly increases the severity of the problem in terms of extent of nerve damage and visible grade 2 disability [57].

In another recent RCT, 42 individuals with T1R were randomized to receive methylprednisolone followed by oral prednisolone ( $n = 20$ ) or oral prednisolone alone ( $n = 22$ ) [58]. There were no significant differences in the rate of occurrence of adverse events or clinical improvement at the completion of the study. However, individuals treated with methylprednisolone were less likely than those treated with prednisolone alone to experience deterioration in sensory function between day 29 and day 113 of

the study. The study also demonstrated that 50% of individuals with T1R and/or NFI required additional prednisolone despite treatment with 16 weeks of corticosteroids. Thus, this study also lends further support to the use of more prolonged courses of corticosteroid to treat NFI in T1R. However, the results of this small study should be used with caution. The study was underpowered and, thus, limited the ability to detect significant differences of less than 30% between the groups.

### Implications for clinical practice

On the basis of the results of these studies, the patient should be informed that the routine use of steroids may only have short-term benefits. Surprisingly, despite the corticosteroids having many known adverse effects, it has been consistently found that the incidence of adverse reaction with steroids is no greater than that with placebo. More than one study has suggested that a more prolonged course of steroids would be more efficacious in improving nerve function without significantly increasing the risk of adverse effects. However, most of the studies were too small to lead to robust evidence. Studies are needed to confirm the long-term effect of using steroids.

### Does any intervention have clinically beneficial outcome in the healing of trophic ulcers in patients with leprosy?

#### Efficacy

One systematic review was retrieved [59]. Eight randomized trials with a total of 557 participants were included. The interventions and outcome measures were diverse. Although three studies that compared zinc tape with more traditional dressings found some benefit, none of these showed a statistically significant effect. One trial indicated that topical ketanserin had a better effect on wound healing than clioquinol cream or zinc paste (RR, 6.00; 95% CI, 1.45–24.75). Two trials comparing topical phenytoin and saline dressing found statistically significant effects in favor of phenytoin for healing of ulcer (standardized mean difference [SMD],  $-2.34$ ; 95% CI,  $-3.30$  to  $-1.39$ ; SMD,  $-0.79$ ; 95% CI,  $-1.20$  to  $+0.39$ ). Canvas shoes were not significantly better than PVC boots, and double rocker shoes did not promote healing significantly more than below-knee plasters.

### Drawbacks

Three studies – one on topical ketanserin versus clioquinol cream or zinc paste [60], one on topical phenytoin versus saline dressing [61], and the third study comparing zinc tape versus gauze with Eusol [62] – reported that no adverse effects of the treatment were observed, while no other included study reported adverse effects at all.

### Comment

Most of the trials were found to have poor methodological quality with a high risk of selection and detection bias [63]. Only two trials seemed to have taken measures to blind outcome assessors. In half the studies the authors did not or failed to show that the groups were comparable at baseline. Two studies clearly had such losses to follow-up that it could be detrimental to the validity of results, while another study was unclear as to how many participated in the analyses. Studies with losses of 20% or below were rated as having adequate follow-up. In fact, only one study [61] out of the eight would conform to the CONSORT guideline [52]. Overall, the

inadequate reporting of the trials could be a threat to the validity of this systematic review.

Topical ketanserin may be more effective than clioquinol cream or zinc paste and topical phenytoin may be more effective than saline dressing in ulcer healing. However, this is based on very weak evidence. For topical ketanserin, only one study tested the comparison; and for phenytoin, the summary analysis of two studies did not show a clear effect. For the other comparisons the results were equivocal. Three studies reported that no adverse effects of treatment were observed.

A recent RCT on the effect of low-level laser therapy with an indium–gallium–aluminum phosphide semiconductor laser on the healing of ulcers in 13 leprosy patients found no statistical difference with the control group who received routine wound care with sterile dressing [64].

### Implications for clinical practice

There is a lack of high quality research in the field of ulcer prevention and treatment in leprosy. Weak evidence suggests that topical ketanserin may be more effective than clioquinol cream or zinc paste, and topical phenytoin may be more effective than saline dressing in trophic ulcer healing in leprosy. Low-level laser therapy does not have any additional benefits to conventional wound care. New trials should be taken up that follow current standards for design and reporting of RCTs.

### Does decompressive surgery have any additional benefit to oral steroids in the treatment of nerve damage of less than 6 months' duration in leprosy?

#### Efficacy

One systematic review was identified [65]. Two RCTs involving 88 participants were included in the review. One trial compared the added benefit of medial epicondylectomy over corticosteroids for participants with ulnar neuritis of less than 6 months' duration [66]. The other trial compared the added benefit of longitudinal epineurotomy over corticosteroids for participants with ulnar, median, common peroneal, or posterior tibial nerve involvement of less than 6 months' duration [67]. The interventions and outcomes were too heterogeneous to be combined in a meta-analysis. After 2 years of follow-up there was only very low-quality evidence of no significant difference in nerve function improvement between participants treated with surgery plus prednisolone or with prednisolone alone.

#### Drawbacks

Adverse effects of decompressive surgery were not adequately described in any of the reports. One study [67] excluded a participant with hemorrhage during the course of the trial, but it was unclear whether this was due to the intervention. The literature reviewing decompressive surgery in leprosy often does not take adverse effects into account, but stresses the importance of having adequate techniques and instruments and competent surgeons to prevent unfavorable outcomes [68]. Complications of decompressive surgery in general may be painful scars, wound problems, hematoma, infection, and damage to nerves, arteries, or tendons [69].

#### Comment

The number of participants in both the trials was too small to allow subgroup analysis. The variability between studies and the limita-

tions in study design and sample size made it difficult to draw any robust conclusions. None of the trials found a significant improvement in improved nerve function between surgical decompression and prednisolone-only groups after a follow-up of 1 or 2 years. This result may have been biased by the selection criteria used for inclusion of patients and nerves. Only about 10% of the cases of neuritis may benefit from decompressive surgery and show improvement after surgery [65]. Not all nerves need decompression. By taking all nerves together, the results might have been misleading.

### Implications for clinical practice

Surgical decompression is used for treating nerve damage in leprosy, but the available evidence from RCTs is of very low quality and does not show any significant added benefit of surgery over steroid treatment alone. Well-designed RCTs are required to establish the effectiveness of the combination of surgery and medical management compared to medical treatment alone.

### In endemic areas, is chemoprophylaxis effective in preventing leprosy?

#### Efficacy

One recent systematic review was retrieved [70], which identified 320 references, from which seven RCTs with a total of 66 311 participants were included and evaluated. The combined results from the RCTs favored chemoprophylaxis to placebo with 2–4 years of follow-up (six RCTs; 66 107 participants; RR, 0.59; 95% CI, 0.50–0.70;  $I^2 = 0$  [ $I^2$  represents percentage total variation across studies caused by heterogeneity]). SDR (21 711 participants; RR, 0.43; 95% CI 0.28–0.67; number needed to treat, 285), dapsones once or twice weekly for at least 2 years (three RCTs; 43 137 participants; RR, 0.60; 95% CI, 0.48–0.76;  $I^2 = 0$ ), and acedapsone every 10 weeks for 7 months (two RCTs; 1259 participants; RR, 0.49; 95% CI, 0.33–0.72;  $I^2 = 0$ ) were significantly superior to placebo in preventing secondary cases of leprosy.

#### Drawbacks

Particularly with dapsones, chemoprophylaxis was often continued for several years after the index case was cured; side effects, compliance, and drug resistance would therefore be likely to cause significant long-term problems if such a strategy were to be implemented.

#### Comment

Almost all of the clinical trials that were performed in the 1960s and 1970s used dapsones alone, at a time when dapsones resistance was high. The duration of follow-up was also limited to a few years, and it is possible that chemoprophylaxis may simply delay the onset of leprosy. Most of the RCTs were judged as having an unclear risk bias. Only one RCT was found with low risk of bias [71]. The latter was a single-centre, double-blind, cluster-randomized, placebo-controlled trial, named COLEP, that was carried out among 28 092 close contacts of 1037 patients in Bangladesh. The number of contacts that were finally included who fulfilled the study requirements was 21 711. SDR or placebo was given to the participants in the second month of starting the index patient's treatment, with follow-up for 4 years. The overall reduction in incidence of leprosy using a single dose of rifampicin in the first 2 years was 57% (95% CI, 0.33–0.72). The groups did not differ between 2 and 4 years. The number needed to treat to prevent a single case of leprosy among contacts was 285 (RR, 0.43; 95% CI, 176–537). In years 3 and 4, no statistically significant difference was found between the numbers

of new cases in the groups. Thus, it was concluded that a single dose of rifampicin given to contacts of patients with newly diagnosed leprosy was effective at preventing the development of clinical leprosy at 2 years. The effect was maintained, but no significant difference was seen between the placebo and rifampicin groups beyond 2 years. However, the total impact of the intervention was still statistically significant ( $P = 0.025$ ) after 6 years and no excess cases were observed in the SDR arm at a later stage [72]. The intervention prevented leprosy in contacts that actually received SDR, but did not offer protection to members of the same contact group who did not take chemoprophylaxis. The cost-effectiveness of SDR prophylaxis was assessed in the COLEP study by calculating the incremental cost-effectiveness ratio between the standard MDT program with the additional chemoprophylaxis intervention versus the standard MDT program only [73]. It was found that chemoprophylaxis with SDR for preventing leprosy among contacts of newly diagnosed leprosy patients was cost-effective at all contact levels and thereby a cost-effective prevention strategy.

In another RCT, which was too heterogeneous to be analyzed along with the other trials, serological response to chemoprophylaxis with a single dose of ROM (among adults above 15 years) and SDR (by body weight, among children up to 15 years) among seropositive extended contacts ( $n = 300$ ) of new leprosy cases was compared with placebo by testing for immunoglobulin M antibodies using the natural trisaccharide phenyl propionate-bovine serum albumin enzyme-linked immunosorbent assay test in Myanmar [74]. The mean optical density titers before and after chemoprophylaxis were 0.24 versus 0.10 and 0.20 versus 0.09 in the treated and nontreated groups, respectively, in adults ( $P = 0.004$ ), and 0.25 versus 0.11 and 0.22 versus 0.11, respectively, in children ( $P = 0.18$ ) after 1 year. These were 0.24 versus 0.17 and 0.20 versus 0.19 ( $P = 0.0005$ ) and 0.25 versus 0.19 and 0.22 versus 0.20 respectively in children ( $P = 0.103$ ) after 2 years. The difference of mean antibody titers before and after single-dose ROM chemoprophylaxis in the treated group was significantly reduced compared with the nontreated group in adults (204 participants; mean difference, 0.06; 95% CI, 0.04–0.08) but was not significant with SDR prophylaxis in children (96 participants; mean difference, 0.04; 95% CI, 0.01–0.09).

### Implications for clinical practice

In endemic areas, chemoprophylaxis using oral dapsone or intramuscular acedapsone for household contacts may provide up to 60% protection against leprosy. SDR in contacts of newly diagnosed patients of leprosy was 57% effective at preventing the development of leprosy after 2 years. A 6-year follow-up suggested that the impact of the SDR chemoprophylaxis was still significant at that time. Chemoprophylaxis with SDR given to contacts of newly diagnosed leprosy patients is also a proven cost-effective intervention strategy at all contact levels. Single-dose ROM chemoprophylaxis in adult extended contacts of leprosy patients has shown significant serological response at 2 years of follow-up.

### Is bacille Calmette–Guérin effective in the prevention of leprosy?

#### Efficacy

A systematic review has been published with evidence from both clinical trials and observational studies [75]. Seven clinical trials (RCTs or controlled trials) were included in the meta-analysis. The risk of leprosy in the bacille Calmette–Guérin (BCG) group was significantly lower than that in the placebo group (pooled RR, 0.74;

95% CI, 0.63–0.86) (Figure 49.2). The authors also carried out a meta-analysis of 19 observational (cohort and case–control) studies. The results supported the conclusion from the clinical trials, with better statistical power and larger preventive effects (RR, 0.39; 95% CI, 0.30–0.49). A meta-analysis published later, which took into account 22 studies (six trials, two cohort studies, and 14 case–control studies), also reached similar conclusions [76].

### Drawbacks

BCG vaccine is not free from adverse effects. Fatal disseminated BCG infection has been reported among people with HIV infection [77]. As with other vaccines, the risk of using BCG will need to be assessed against its benefits.

### Comment

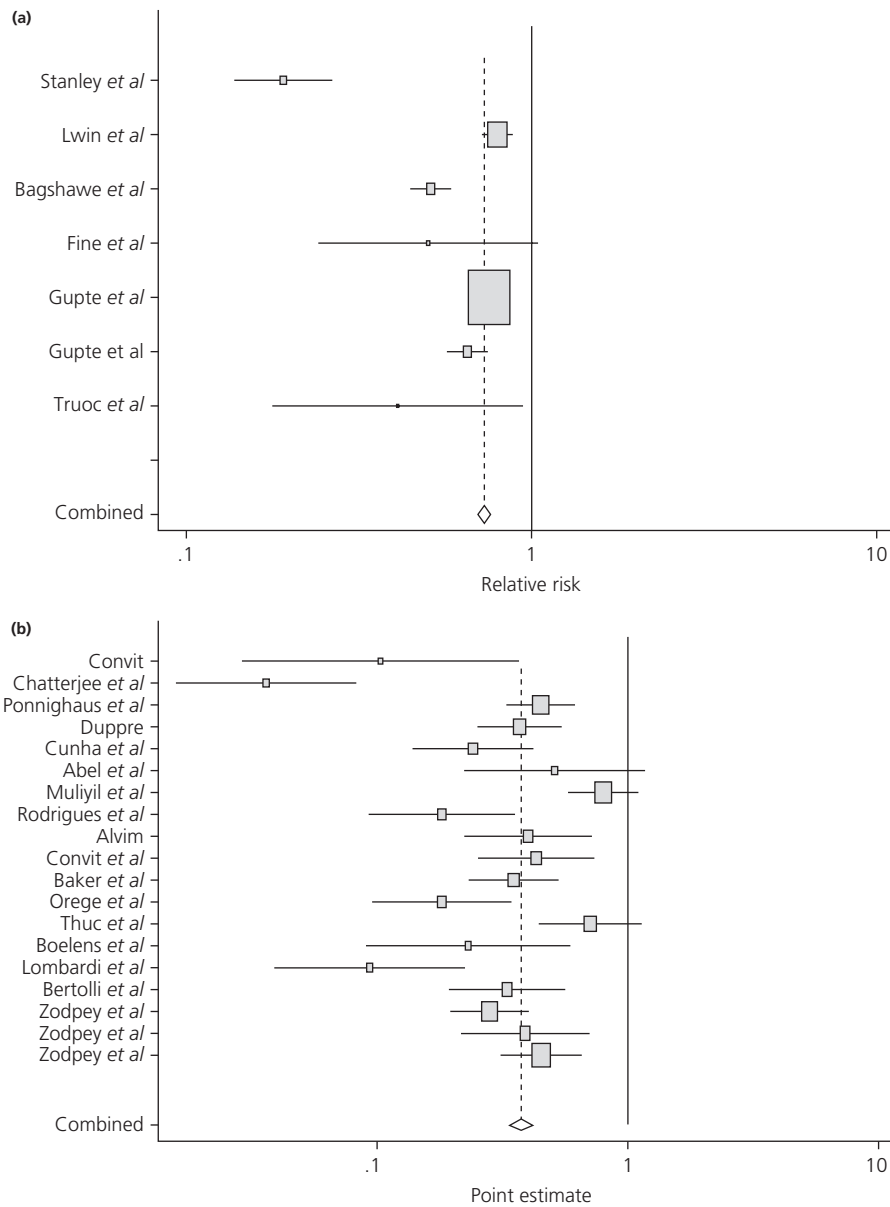

The BCG vaccine contains a mycobacterium that is closely related to *M. leprae* and is recommended by the WHO's Expanded Programme on Immunization for protection against tuberculosis. It is routinely used to vaccinate children in countries in which leprosy continues to be a public health problem, and it is currently recommended for the household contacts of leprosy patients. It has been well investigated in RCTs, cohort studies, and case–control studies. The evidence from different studies uniformly supports the use of BCG to prevent leprosy, although the size of the effect in different studies varies, possibly due to differences in the study designs and populations involved. However, the utility of repeat or booster BCG vaccinations is still unclear. In a cluster randomized community trial in Brazil, with 6 years and 8 months of follow-up, 99 770 school children with neonatal BCG were inducted, among whom 42 662 were in the revaccination arm [78]. The incidence rate ratio of leprosy in the intervention over the control arm within the follow-up, controlled for potential confounders and adjusted for clustering, was 0.99 (95% CI, 0.68–1.45). Thus, there was no evidence of protection conferred by the second dose of BCG vaccination in school children against leprosy during the trial follow-up. In another interesting offshoot of the COLEP trial mentioned earlier, both univariate and multivariate analysis of the trial data showed that a protective effect was seen in contacts that received either SDR or BCG, compared with contacts with no intervention (BCG-adjusted protective effect was 57% (95% CI, 24–75%); for SDR 58% (95% CI, 30–74%)) [79]. In contacts receiving both the interventions, the protective effect was 80% (95% CI, 50–92%). Thus, there is a demonstrated additive effect of immunoprophylaxis by routine infancy BCG vaccination and chemoprophylaxis with SDR given to close contacts of newly diagnosed leprosy patients.

### Implication of clinical practice

Given its protective effects and easy availability, BCG vaccination is warranted in regions in which leprosy continues to be a public health problem and in household contacts who are at greater risk of acquiring the infection. However, there is no evidence that BCG revaccination would offer additional protection. Instead, SDR has a demonstrated additive effect to BCG vaccination in infancy in providing protection in close contacts of newly diagnosed leprosy patients.

### Acknowledgments

I would like to gratefully acknowledge the original contribution of Shamez Ladhani and Weiya Zhang, the authors of this chapter in the previous edition of the book. I have kept their template and much of the background material intact.

**Figure 49.2** Meta-analyses of clinical trials (a) and observational studies (b) on the role of BCG in the prevention of leprosy. The rectangles represent the point estimates for each study, the size of the rectangle represents the weight allocated to each study, and the horizontal lines represent the 95% confidence intervals. The diamond and vertical broken line represent the summary estimate and the size of the diamond represents the 95% confidence intervals of the summary estimate. The solid vertical line is the null value. (Reproduced with permission from Setia *et al.*, 2006 [75]. Reproduced with permission from Elsevier.)

## Key points

- Although chemotherapy is the main treatment for leprosy, there is a lack of robust placebo-controlled trials.
- MDT may be useful to speed up clinical improvement, but may offer no greater benefit than single agents in bacterial clearance.
- WHO-MDT is superior to the single-dose regimen of ROM with regard to clinical improvement and rate of relapse in MB leprosy.
- There is no evidence that 6-month U-MDT is as efficacious or safe as the current 12-month WHO-MDT with regard to MB leprosy.
- Current evidence would support the use of thalidomide in moderate to severe ENL. However, it must not be used in women of childbearing age and it has to be monitored carefully because of its neuropathic side effects.
- There is no ground for preferring the use of corticosteroids in ENL over other effective interventions like thalidomide or clofazimine.
- Routine use of steroids may only have short-term benefits in improving nerve function impairment in leprosy.
- Weak evidence suggests that topical ketanserin may be more effective than clioquinol cream or zinc paste, and topical phenytoin may be more effective than saline dressing in trophic ulcer healing in leprosy.
- Surgical decompression is used for treating nerve damage in leprosy, but the available evidence from RCTs does not show any significant added benefit of surgery over steroid treatment alone.
- Chemoprophylaxis with SDR given to contacts of newly diagnosed leprosy patients is efficacious and also a proven cost-effective intervention strategy at all contact levels.
- BCG is effective in preventing leprosy. It is recommended to protect people from the infection in endemic areas or among household contacts. However, revaccination with BCG does not afford additional protection.
- Care has to be taken when extrapolating the evidence to developed countries, as most of the studies have been carried out in developing countries, and in regions where leprosy is endemic.

<sup>3</sup> Leishmaniasis Clinical Program, Drugs for Neglected Diseases initiative (DNDi), Geneva, Switzerland

## Background

### Definition

Leishmaniasis is a group of diseases caused by infection with protozoan parasites called *Leishmania*, transmitted by bites from sandflies infected with the microorganisms [1,2]. The parasite may be transmitted from person to person or from a range of animals to humans. Leishmaniasis is globally a poverty-related disease and is associated with war, malnutrition, displacement, poor housing, illiteracy, and gender discrimination. Leishmaniasis is also linked to environmental changes and migration to endemic areas.

There are several clinical presentation forms, which are associated with a broad range of signs, symptoms, and degrees of severity. Cutaneous leishmaniasis (CL) is the most common form of presentation. After an incubation period of 1–12 weeks, a papule develops at the site of the insect bite. The papule grows and turns into an ulcer (Figures 50.1 and 50.2). Most patients have one or two lesions, usually on exposed parts of the body such as the face, arms, or legs, varying in size from 0.5 to 3 cm in diameter. Usually, lesions heal spontaneously over months or years, leaving a permanent atrophic scar.

### Incidence/prevalence

The World Health Organization considers leishmaniasis to be one of the most serious parasitic diseases, with consequences for socio-economic development in many tropical and subtropical developing countries [3,4]. Until recently, the public health impact of leishmaniasis was grossly underestimated. During the past years, the endemic regions have been spreading and there has been a sharp increase in the number of recorded cases of the disease. Approximately 350 million people are at risk of contracting the disease. CL is endemic in many countries in the Mediterranean area, the Middle East, large parts of the Indian subcontinent, Africa, and Central and South America. An estimated 1.5 million new cases of CL occur annually. However, a substantial number of cases are not recorded, as notification of the disease is compulsory in only 32 of the 98 affected countries.

## Etiology and prognosis

More than 20 recognized *Leishmania* species are responsible for both forms of visceral and cutaneous leishmaniasis in 98 countries, each one having distinct epidemiological and demographic patterns [5]. The geographical distribution of the species causing CL affects countries and territories in North Africa, the Mediterranean, the Middle East, north-eastern India, and Central Asia (the Old World), the main species are *L. major*, *L. tropica*, and *L. aethiopica*, and less frequently *L. infantum* and *L. donovani*. In Central and South America, from Texas, USA, to the north of Argentina, there are two *Leishmania* subgenera: the subgenus *Leishmania* (*Leishmania*) with *L. mexicana* and *L. amazonensis* among the main pathogenic species, and subgenus *Leishmania* (*Viannia*), with four main species, *L. braziliensis*, *L. panamensis*, *L. guyanensis*, and *L. peruviana*. The different presentations of leishmaniasis vary in their prognosis and response to therapy. In general, half of the lesions caused by *L. major* or *L. mexicana* will heal within 3 months, while those caused by *L. tropica* take longer, about 10 months, and those due to *L. braziliensis* persist much longer.

### Diagnostic tests

Clinically diagnosed CL cases should be confirmed using the traditional diagnostic techniques of smear, culture, and/or histological analysis of skin biopsies [6,7]. The polymerase chain reaction test appears to be the most sensitive single diagnostic test for skin samples and aids in identifying the infecting species. Antibodies in circulation are, in general, low or undetectable. The leishmanin test (Montenegro test) detects delayed-type hypersensitivity response; it is simple to use and highly specific, but produces negative results in some affected patients and does not distinguish between previous and current infections, which is the reason why its use remains for epidemiological studies.

### Aims of treatment

Many different treatments for CL have been described [8,9]. The pentavalent antimony derivatives meglumine antimoniate (Glucantime®, Sanofi) and sodium stibogluconate (Pentostam®

Figure 50.1 Cutaneous leishmaniasis.

produced by GSK, and the generic SSG, produced by Albert David, India) remain the mainstay of treatment. Treatments are expensive and require administration over long periods of time. An effective treatment in one area for a given organism may not work in a different geographical area or for a different organism in the same area. In these cases, efficacy also depends on the patient's response. Topical treatments are appropriate for early self-limiting lesions that are not at risk of dissemination, and are attractive options offering reduced systemic toxicity and outpatient treatment. Systemic treatments are indicated when the patient has multiple or complicated lesions or is at risk of mucocutaneous leishmaniasis. The development of drug resistance is a major concern.

### Methods of search

We included all randomized controlled trials (RCTs) by searching the Cochrane Library (July 2012), Medline (1966–July 2012), and Embase (1988–July 2012). We also use the two Cochrane systematic reviews of RCTs on interventions for Old World and American CL published in 2008 and 2009, respectively [10,11]. Respecting the last edition of this book, we have found 30 new RCTs on Old World CL and 12 RCTs on American CL.

## Questions

### What is the randomized controlled trial evidence for local treatments in Old World cutaneous leishmaniasis?

#### Efficacy

##### *Intralesional meglumine antimoniate (Glucantime) or sodium stibogluconate (Pentostam)*

We found two RCTs comparing local versus systemic therapy with antimonials. An RCT [12] in Saudi Arabia (*L. major*) compared intralesional meglumine antimoniate 0.2–0.8 mL/lesion every other day over a 30-day period with 12 intramuscular injections of 15 mg/kg per day meglumine antimoniate 6 days a week. Complete cure at the end of treatment was in 68.6% (48/70) and 59.7% (46/77) of lesions, respectively. An RCT [13] from Afghanistan compared intralesional stibogluconate for up to 29 days with intramuscular stibogluconate daily for 21 days. Two months after treatment, results showed complete cure of participants in 47.3% (70/148) and 18% (26/144) of the intralesional and intramuscular stibogluconate groups, respectively.

Figure 50.2 Ulcerative cutaneous leishmaniasis.

ralesional stibogluconate for up to 29 days with intramuscular stibogluconate daily for 21 days. Two months after treatment, results showed complete cure of participants in 47.3% (70/148) and 18% (26/144) of the intralesional and intramuscular stibogluconate groups, respectively.

An RCT [14] in Pakistan (*Leishmania* spp. not reported) compared different intralesional therapeutic regimens – that is, weekly intralesional meglumine antimoniate with intralesional meglumine antimoniate fortnightly – both until complete cure or up to 8 weeks. Complete cure 2 months after therapy was observed in 92% (102 of 111) in comparison with 85.6% (89 of 104) of the lesions, respectively.

An RCT from Iran [15] (*Leishmania* not specified) compared conventional intralesional injections of 0.1 mL meglumine antimoniate with mesotherapy gun intralesional injections. There was complete cure at 3 months after treatment in 86.66% (26/85) and 83.33% (25/85) of patients, respectively.

##### *Topical paromomycin (aminosidine)*

We found three RCTs comparing topical paromomycin with placebo. A double-blind RCT [16] from Tunisia (*L. major*) compared 15% paromomycin and 10% urea with placebo twice daily for 14 days. The results at 105 days showed a complete cure in 63% (36/57) and 65.5% (38/58) of the patients, respectively. A big double-blind RCT [17] in Iran (*L. major*) compared 15% paromomycin and 10% urea with a placebo, both twice a day for 14 days. The results at 105 days showed definitive cure in 68% of patients treated with the drug compared with 68% with the placebo. Another small double-blind RCT [18] in Iran (*L. major*) compared 15% paromomycin and 10% urea with placebo twice daily for 30 days. The results at 60 days showed definitive cure in 17% compared with 20% of the patients, respectively.

We found an RCT of different regimens of paromomycin. A double-blind RCT [19] from Iran (*L. major*) compared paromomycin ointment regimens of two applications per day for 4 weeks and for 2 weeks. Complete cure at 105 days was observed in 50% (58/117) compared with 37% (43/116) of the patients, respectively.

We found two RCTs comparing paromomycin with antimonials. An unblinded RCT [20] in Iran (*L. major*) compared topical 15% paromomycin and 10% urea twice per day and intralesional 1.5 g/5 mL meglumine antimoniate weekly for a maximum of 90

days. The results at less than 2 months after treatment showed complete cure in 16.6% (eight of 48) compared with 41.7% (20 of 48), respectively. Another open RCT [21] in Iran (*L. major*) compared topical 15% paromomycin and 10% urea twice per day, with intralesional 1 mL meglumine antimoniate every other day, both for 20 days. The results at 1 week after treatment showed complete cure in 66.7% (20/30) compared with 60% (18/30), respectively.

We found an open RCT [22] from Turkey (*L. tropica*) that compared 15% paromomycin and 12% methylbenzothonium chloride twice per day for 15 days with 400 mg/day oral ketoconazole for 30 days. One month after the end of treatment, there was complete cure in 37.5% (15/40) of patients compared with no complete cure in any of the patients, respectively.

An RCT [23] from Iran (*L. major*) compared topical paromomycin-methylbenzothonium chloride applied topically twice daily for 28 days with topical photodynamic therapy every week for 4 weeks and with placebo topically twice daily also for 28 days. Two months after treatment, there was complete cure in 41.2% (14/34), 93.5% (29/31), and 13.3% (4/30) of lesions, respectively.

### Intralesional zinc sulfate solution

We found four RCTs comparing intralesional zinc sulfate with antimonials. An RCT [24] in Iran (*L. major*) compared 2% zinc sulfate solution with meglumine antimoniate, both with up to six weekly intralesional injections. Five weeks after treatment, there was complete cure in 22.6% (12/53) and 50.9% (27/53), respectively. Another RCT [25] in Iran (*L. major*) compared intralesional 2% zinc sulfate with intralesional meglumine antimoniate. At 6 weeks posttreatment, the complete cure rates were 83.87% and 60%, respectively. An RCT [26] in Iraq compared intralesional 2% zinc sulfate with intralesional 100 mg/mL sodium stibogluconate. After 6 weeks, a total of 94.8% (36/38) compared with 88.5% (31/35) of the lesions were cured, respectively. An RCT [27] from Iran compared 0.2–0.5 mL intralesional 2% zinc sulfate solution per lesion twice within 2 weeks and intralesional Glucantime weekly injected in the lesions for 6 weeks. After 8 weeks, complete cure rates were 33.3% and 80%, respectively.

### Thermotherapy

We found four RCTs comparing thermotherapy with antimonials. An RCT [13] from Afghanistan (*L. tropica*) compared thermotherapy using radiofrequency waves with intralesional stibogluconate for up to 29 days and intramuscular stibogluconate daily for 21 days. Two months after treatment, results showed that complete cure of participants accounted for 54% (75/139), 47.3% (70/148), and 18% (26/144), respectively. An RCT [28] from Iran (*Leishmania* not reported) compared localized heating using a radiofrequency heat generator and intralesional meglumine antimoniate for 4 weeks. Six months after treatment, results showed complete cure of participants in 80.7% (46/57) and 56.7% (34/60), respectively. An RCT [29] performed in Washington, DC, with patients infected in Iraq or Kuwait (*L. major*) compared one session of local 50°C heat therapy with 20 mg/kg per day of intravenous sodium stibogluconate infused over 10–50 min for a total of 10 doses. In an intent-to-treat analysis, the per-subject efficacy at 2 months was 48% and 54%, respectively, and the per-lesion efficacy was 73% and 59%, respectively. Another RCT [30] from Afghanistan (*L. tropica*) compared a single localized treatment of thermotherapy with 5 days of intralesional administration of Glucantime. At 6 months, the cure rates were 82.5% and 74%, respectively.

### Cryotherapy

We found five RCTs comparing cryotherapy with antimonials. An RCT [31] from Iran (*Leishmania* not reported) compared cryotherapy plus intralesional meglumine antimoniate versus cryotherapy and intralesional meglumine antimoniate alone, both every 2 weeks. At the end of the treatment, there was a complete cure of lesions in 80.5% (120/149), 52.2% (120/230), and 52.5% (84/160) in the respective groups. An RCT [32] from Iran (*L. tropica*) in children compared cryotherapy with liquid nitrogen applied twice to the lesion repeated weekly up to 6 weeks with intralesional Glucantime. Complete response rate at 6 months after treatment in the intention-to-treat analysis was 52.5% (21/40) and 25.6% (10/39), respectively. Another RCT [33] from Iran (*Leishmania* not reported) compared a combination of cryotherapy and intralesional meglumine antimoniate with cryotherapy alone and intralesional meglumine antimoniate monotherapy. The authors reported complete cure of participants in 89% (18/20), 67.8% (14/20), and 75% (15/20) of the respective groups, although they did not report the time of this assessment. An RCT [34] from Iran compared a combined triple therapy of cryotherapy, paromomycin cream plus intralesional meglumine antimoniate, with intralesional meglumine antimoniate monotherapy. At 6 weeks after treatment, complete cure of participants was 89.5% (68/81) and 70.4% (57/76) of the respective groups. An RCT [35] from Iran (*L. tropica*), compared CO<sub>2</sub> laser therapy with cryotherapy biweekly plus intralesional meglumine antimoniate weekly. At 12 weeks, complete cure was 93.7% (89/95 lesions) and 78% (74/95 lesions), respectively.

### Antibiotics

An RCT [36] from Iran (*Leishmania* not reported) compared weekly intralesional Glucantime injections (150–600 mg) with weekly intralesional injections of metronidazole (2.5–10 mg). In the former group, 13 patients recovered with eight injections (81%) and in the latter group only three patients recovered with eight injections (16.6%).

An RTC [37] in Iraq (*L. tropica* and *L. major*) compared intralesional injection of ciprofloxacin solution 0.2% (2 mg/mL) with intralesional 7% sodium chloride hypertonic solution. After 8 weeks, lesions assigned to ciprofloxacin showed an 81.5% healing rate with an average scar size reduction of 68.6%. Lesions assigned to sodium chloride treatment were completely healed (with or without scarring) in 76.2% of cases, and, when a scar remained, the scar size was reduced 66.0% compared with the original lesion.

An RTC [38] from Tunisia and France (*L. major*) compared a third-generation aminoglycoside ointment (WR279,396) applied twice daily for 20 days with placebo. At 80 days after treatment, in the intent-to-treat analysis, complete clinical response was observed in 94% (47/50) and 71% (30/42) of participants, respectively.

### Other

We found very limited RCT evidence for the lack of efficacy of treatments such as garlic cream [39], cream containing interferon beta [40], topical opium [41], intralesional interferon gamma [42], topical honey-soaked gauze and intralesional meglumine antimoniate in a duplicated study [43,44], topical 5% imiquimod cream plus intramuscular meglumine antimoniate [45], and topical antifungals [46,47].

We found very limited RCT evidence for the efficacy of a topical herbal extract [48], topical diminazene solution of cetrimide (Savlon) with chlorhexidine [49], intralesional 7% hypertonic

sodium chloride [25,36,50], CO<sub>2</sub> laser [34,51], and trichloroacetic acid [52].

### Drawbacks

Pain (sometimes severe pain) at the site of injection is frequently described in intralesional treatments. No other adverse reactions or local reactions were significantly reported. An appreciable number of cases of irritant contact dermatitis have been reported with topical paromomycin. Postinflammatory hypopigmentation and hyperpigmentation and burns have been described with cryotherapy and thermotherapy.

### Comment

We found 44 RCTs that covered at least 21 different local treatments for Old World CL, which could be broadly categorized into seven main groups: antimonial drugs, topical paromomycin, intralesional zinc sulfate solution, thermotherapy, cryotherapy, antibiotics, and other therapies.

Most of the trials are relatively adequate in size, with short follow-up periods. In comparisons with placebo or no treatment, some trials showed variable rates of self-healing. The results of some of the studies are difficult to interpret owing to unusually low cure rates in the group treated with antimonials.

### Implications for practice

The mainstay of local treatments for Old World CL has been the intralesional injection of antimony compounds, which have been extensively used as controls in RCTs for several newer treatments. Local treatment is appropriate for patients with early, not very inflamed, lesions on cosmetically or functionally important sites, but an expectant approach may also be appropriate in Old World endemic areas, due to rapid spontaneous healing and the development of protective immunity.

To limit toxicity, antimony derivatives have been used intralesionally for localized Old World CL. There are some RCT data on the usefulness of intralesional administration of meglumine antimoniate in comparison with other local and systemic treatments. It was difficult to evaluate the efficacy of any of the multiple current intralesional or intramuscular antimony regimens in the absence of any placebo-controlled trial. Local pain and time-consuming intralesional treatments have led investigators to seek pain-free and easier treatment modalities such as paromomycin ointment, but on the basis of the best evidence it is unlikely to be beneficial.

There is some RCT data on the lack of efficacy of intralesional zinc sulfate. There was some evidence to support the use of photodynamic therapy, thermotherapy, cryotherapy, and topical 5% imiquimod cream as antimonial adjuvant therapies. There was complete absence of RCT evidence for local excision, curettage, electrodesiccation, or other physical therapies.

## What is the randomized controlled trial evidence for systemic treatments in Old World cutaneous leishmaniasis?

### Efficacy

#### *Intramuscular/intravenous meglumine antimoniate or stibogluconate*

We found three RCT comparing different systemic antimonial therapeutic regimens. An RCT [53] performed in Pakistan (*L. tropica*) compared intramuscular meglumine antimoniate (20 mg/kg per day, maximum 850 mg) for 21 days, intralesional meglumine antimoniate (0.5 mL) into each lesion plus intramuscular meglu-

mine antimoniate (20 mg/kg per day, maximum 850 mg) for 21 days, and no treatment. Complete cure was achieved in 55% (11/20), 75% (15/20), and 10% (2/20), respectively. A double-blind RCT [54] performed in Iran (*L. major* and *L. tropica*) compared intramuscular 60 mg/kg per day Glucantime for 3 weeks, intramuscular 30 mg/kg per day Glucantime and 40 mg of the oral omeprazole for 3 weeks, and intramuscular 30 mg/kg per day Glucantime for 3 weeks. Rate of complete response at 12 weeks after treatment was 93%, 89%, and 80%, respectively. A blinded RCT [55] from Iran (*L. major*) compared oral pentoxifylline plus intramuscular meglumine antimoniate with intramuscular meglumine antimoniate for 20 days. Three months after treatment, complete cure of participants occurred in 81.3% (26/32) and 50% (16/32), respectively.

#### *Oral itraconazole*

We found six RCTs comparing oral itraconazole with placebo or no treatment. A small RCT [56] from Kuwait (*L. tropica* and *L. major*) compared 100 mg (or 3 mg/kg) itraconazole with placebo, both twice per day for 6–8 weeks. The results, 12 weeks after treatment, were excellent in 73% (11/15) and good in 20% (3/15) of the patients, in comparison with no signs of improvement in the placebo group. A big double-blind RCT [57] in Iran (*L. major*) compared 200 mg/day itraconazole for 8 weeks with placebo. Three months after treatment, results showed complete cure of participants in 67% (67/100) and 53% (53/100) of the respective groups. In a double-blind RCT [58] in Iran (*L. tropica* and *L. major*), 7 mg/kg per day itraconazole for 3 weeks was compared with placebo. One month after treatment, the lesions in 55% (36/65) of the patients showed a clinical and biological response compared with 41% (27/66), respectively. A small double-blind RCT [59] in India (*L. major* and *L. tropica*) compared oral itraconazole 100 mg twice per day for 6 weeks with placebo. Three months after treatment, results showed complete cure of participants in 70% (7/10) and 10% (1/10) of the respective groups. Finally, a small RCT [60] in India (*L. major* and *L. tropica*) compared 4 mg/kg per day itraconazole for 6 weeks with placebo. At the end of the treatment period, complete cure of participants occurred in 75% (15/20) and 0% (0/20) in the oral itraconazole and placebo groups, respectively. A small RCT [61] in India (*L. tropica*) compared 4 mg/kg per day itraconazole for 6 weeks with a few untreated patients. The results showed that 66.6% (10/15) of the patients were cured in comparison with no significant changes, respectively.

#### *Oral ketoconazole*

A small RCT [62] in Kuwait (*Leishmania* not reported) using oral 600 mg/day ketoconazole for 28 days was compared with oral 800 mg/day ketoconazole for 28 days. The authors did report complete cure of 66.7% (12/18) and 60% (9/15) participants in the respective groups at the end of the treatment period.

We found two RCTs comparing oral ketoconazole with antimonials. An RCT [63] in Iran (*L. tropica* and *L. major*) compared ketoconazole 600 mg/day for 30 days with intralesional meglumine antimoniate, six to eight injections biweekly. Six weeks after treatment there was a complete cure of 89% (57/64) and 72% (23/32) of participants in the respective groups. An RCT [64] in Yemen (*Leishmania* not reported) compared intralesional stibogluconate (100 mg/mL) alone, a combination of intralesional stibogluconate plus intramuscular stibogluconate, and a combination of intralesional stibogluconate plus oral ketoconazole (200 mg three times daily) for 4 weeks. Complete cure occurred in 58.3%, 93.3%, and 92.3% of lesions, respectively.

We found an open RCT [21] from Turkey (*L. tropica*) comparing 15% paromomycin and 12% methylbenzothonium chloride twice per day for 15 days with oral ketoconazole 400 mg/day for 30 days. At 4 weeks of treatment, any patient showed complete cure in the group of oral ketoconazole compared with 37.5% of patients (15 of 40) in the other group.

### Oral fluconazole

In a double-blind RCT [65] in Saudi Arabia (*L. major*), oral fluconazole 200 mg/day for 6 weeks was compared with placebo. At 3 months after treatment, complete cure of participants occurred in 63/106 (59%) and 22/103 (21%), respectively.

An RCT [66] in Iran (*L. major*) compared oral fluconazole 400 mg daily with oral fluconazole 200 mg daily. At 6 weeks, complete healing in the 400 mg group was significantly higher than in the 200 mg group (81% vs 48.3%).

### Oral dapsone

We found three RCTs comparing oral dapsone with placebo or no treatment. A double-blind RCT [67] in India (*L. major* and *L. tropica*) compared 100 mg dapsone every 12 h for 6 weeks with placebo. At 1 month after therapy, complete cure was seen in 82% (49/60) and 5% (3/60) of patients, respectively. A small RCT [59] in India (*L. major* and *L. tropica*) compared dapsone 4 mg/kg per day, itraconazole, and placebo, all for 6 weeks. Three months after therapy, complete healing was assessed in 90% (18/20), 75% (15/20), and 10% (2/20) of the patients, respectively. An RCT [68] from India (*L. tropica*) compared dapsone 2 mg/kg per day for 21 days with untreated patients. Six months after therapy, results showed cure in 80% (40/50) of the patients and failure in 10% (5/50), compared with no significant changes, respectively.

### Oral allopurinol

We found three RCTs comparing oral allopurinol with systemic antimonials. An RCT [69] in Iran (*L. tropica*) compared oral allopurinol 15 mg/kg per day for 3 weeks, intramuscular meglumine antimoniate 30 mg/kg per day for 2 weeks, and allopurinol plus meglumine antimoniate. At the end of the treatment period, complete cure of participants was in 18% (9/50), 24% (12/50), and 46% (23/50) of the respective groups. An open RCT [70] from Iran (*L. major*) compared allopurinol 20 mg/kg per day plus meglumine antimoniate 30 mg/kg per day with intramuscular meglumine antimoniate 60 mg/kg per day, both for 20 days. At 51 days after treatment there was a complete cure of participants in 69% (25/36) and 72% (26/36) of the respective groups. An RCT [71] in Pakistan (*Leishmania* not reported) compared oral allopurinol 20 mg/kg per day in three or four doses with intravenous stibogluconate 20 mg/kg per day, both for 15 days. At the end of the treatment period there was a complete cure of participants in 85% (17/20) and 70% (14/20) of the respective groups.

### Oral miltefosine

An RCT [72] from Iran (*L. major*) compared oral miltefosine for 28 days with intramuscular meglumine antimoniate for 14 days. Three months after treatment the results showed complete cure in 81.3% (26/32) and 80.6% (25/31) of participants, respectively.

### Oral antibiotics

An RCT [73] performed in Iran (*L. tropica*) compared 500 mg/day oral azithromycin for 5 days/month; treatment cycles were repeated

monthly to a maximum of 4 months with 60 mg/kg intramuscular meglumine antimoniate for 20 days. At 16 weeks, the response rates in the azithromycin group of 20 patients (29 lesions) were as follows: full improvement, 10.3%; partial improvement, 27.6%; and 62.1%, no response. In the intramuscular meglumine antimoniate group with 27 patients (58 lesions), these rates were 34.4%, 13.8%, and 51.7%, respectively.

We found three RCTs comparing oral rifampicin with placebo. An RCT [74] from Saudi Arabia (*Leishmania* not reported) compared oral rifampicin for 4–6 weeks with placebo. Three months after treatment the results showed complete cure occurred in 45.7% (21/46) and 18.8% (3/16), respectively. An RCT [75] from India (*L. tropica*) compared oral rifampicin for 4 weeks with placebo. At the end of the treatment there was complete cure in 68% (17/25) and 4% (1/25) of the participants, respectively. Another trial [76] from India (*L. tropica*) which compared oral rifampicin plus omeprazole for 6 weeks with placebo reported at the end of the treatment a complete cure of 64% (16/25) and 12% (3/25) of participants, respectively.

### Other

We found very limited RCT evidence for the benefit of oral zinc sulfate [77,78] and 100 mg artesunate plus 250 mg/12.5 mg sulfamethoxypyrazine/pyrimethamine [79].

### Drawbacks

Parenteral antimonials can produce nausea, vomiting, anorexia, diarrhea, myalgia, body aches, and liver abnormalities. The most common side effects with oral antifungals were gastrointestinal complaints and headache, but the same symptoms were reported in patients from the placebo group and none of the laboratory values were outside normal limits. With oral dapsone, side effects include nausea and anemia. With oral allopurinol, side effects include nausea, macular rash, heartburn, and a mild increase in liver enzymes. With oral miltefosine the side-effects include nausea, vomiting, abdominal pain, headache, itch, and fever.

### Comment

We found 29 RCTs that covered at least 11 different systemic treatments for Old World CL, which could be broadly categorized into nine main groups: antimonial drugs, oral itraconazole, oral ketoconazole, oral fluconazole, oral dapsone, oral allopurinol, oral miltefosine, oral antibiotics, and other therapies.

We have some concerns regarding the precision of data reported in several studies, and again unusually low cure rates in the group treated with antimonials, as well as variable rates of self-healing.

### Implications for practice

Systemic therapy in Old World CL is appropriate for patients with multiple or more complicated lesions. In these cases, pentavalent antimony compounds have been regarded as the first-line therapy. Their efficacy has been established in RCTs in comparison with other treatments, but not in comparisons between different antimonials or in comparison with a placebo.

When well tolerated and oral agents are needed or preferred, there is limited–moderate RCT evidence to support the use of oral itraconazole or fluconazole, 200 mg/day for 6–8 weeks and oral pentoxifylline as adjuvant therapy to intramuscular meglumine antimoniate. There was insufficient evidence to support the use of oral therapy with dapsone or allopurinol, miltefosine, or rifampicine.

## What is the randomized controlled trial evidence for systemic treatments in American cutaneous leishmaniasis?

### Efficacy

#### *Intravenous/intramuscular meglumine antimoniate*

We found two RCTs comparing different doses of meglumine antimoniate. An RCT [80] from Colombia (*L. panamensis*) compared 20 mg/kg per day intramuscular meglumine antimoniate once a day for 10 days with 20 mg/kg per day intramuscular meglumine antimoniate for 20 days. At 52 weeks after treatment the results showed responses in 41% (28/68) and 35% (24/68) of patients, respectively. In a small double-blind RCT [81] from Brazil (*L. braziliensis*), a high dose of intravenous meglumine antimoniate (20 mg/kg per day) was compared with a low dose of intravenous meglumine antimoniate (5 mg/kg per day), both for 30 days. At the end of treatment the results showed complete responses in 81.8% (9/11) and 83.3% (10/12) of the patients, respectively.

We found two RCTs comparing intramuscular meglumine antimoniate with intramuscular stibogluconate. In an RCT [82] in Panama (*L. braziliensis panamensis*), 20 mg/kg per day intramuscular meglumine antimoniate was compared with 20 mg/kg per day intramuscular stibogluconate, both for 20 days. At the end of treatment the results showed complete cure in 72% (21/29) and 46% (14/30) of the patients, respectively. A double-blind RCT [83] in Bolivia and Colombia (*L. braziliensis*) compared 20 mg/kg per day intramuscular meglumine antimoniate; 20 mg/kg per day intramuscular stibogluconate (Pentostam), and stibogluconate (generic), all for 20 days. At 6 months the results showed complete cure in 76% (38/50), 75% (12/16), and 83% (40/48) of patients, respectively.

#### *Intravenous/intramuscular stibogluconate*

We found two RCTs comparing different doses of stibogluconate. A small double-blind RCT [84] in Panama and Central America (*L. braziliensis panamensis*) compared 10 mg/kg per day stibogluconate, with 20 mg/kg per day stibogluconate, both for 20 days. Complete cure occurred in 76% (16/21) and 100% (19/19) of participants in the respective groups 1.5 months after treatment. A small RCT [85] of US military personnel compared 600 mg intravenous stibogluconate once daily for 10 days by rapid infusion, 600 mg/day intravenous stibogluconate followed by a continuous infusion of 600 mg stibogluconate for 24 h every day for 9 days, and stibogluconate loading dose of 600 mg followed by 200 mg stibogluconate every 8 h for 9 days. Complete cure occurred in 100% (12/12), 50% (6/12), and 42% (5/12) of participants in the respective groups at the end of treatment. A small RCT [86] of US military personnel was excluded because of mixed Old World and American forms of CL.

#### *Intravenous/intramuscular paromomycin*

We found two RCTs comparing paromomycin with antimonials. A small open RCT [87] in Brazil (*L. braziliensis*) compared 4 mg/kg per day intramuscular pentamidine on alternative days up to a total of eight injections, 20 mg/kg per day intramuscular paromomycin for 20 days, and 10 mg/kg per day intramuscular meglumine for 20 days. At 3 years after the end of treatment, all of the patients in the paromomycin and pentamidine groups were cured. An open RCT [88] in Belize (*L. braziliensis* and *L. mexicana*) compared intravenous paromomycin 14 mg/kg per day with intravenous sodium stibogluconate 20 mg/kg per day, both for 20 days. Complete cure occurred in 59% (10/17) and 88% (15/17) of participants in the respective groups 1.5 months after treatment.

An RCT [89] from Colombia (*L. panamensis*) compared parenteral 12 mg/kg per day paromomycin for 7 days, parenteral 12 mg/kg per day paromomycin for 14 days, and parenteral paromomycin 18 mg/kg per day for 14 days. At 12 months after treatment the results showed cures in 10% (3/30), 45% (13/29), and 50% (15/30) of patients, respectively.

#### *Oral ketoconazole*

An RCT [90] in Guatemala compared 600 mg/day oral ketoconazole for 28 days, 20 mg/kg per day intravenous stibogluconate for 20 days, and placebo. Complete cure occurred in 52% (12/23), 96% (24/25), and 20% (3/15) of participants in their respective groups 2 months after treatment. Another RCT [91] from Panama (*L. braziliensis*, *L. panamensis*) compared oral 600 mg/day ketoconazole for 28 days, 20 mg/kg intramuscular stibogluconate for 20 days, and placebo. At 3 months the results showed cures in 73% (16 of 22), 68% (13 of 19), and none of the patients, respectively.

#### *Oral allopurinol*

We found three RCTs comparing oral allopurinol with meglumine antimoniate. An open RCT [92] in Colombia (*L. braziliensis panamensis*) compared 20 mg/kg per day intramuscular meglumine antimoniate for 15 days, oral allopurinol plus 20 mg/kg per day intramuscular meglumine antimoniate in four divided doses for 15 days, 20 mg/kg per day oral allopurinol in four divided doses for 15 days, and untreated patients. At 12 months after treatment the results showed cures in 36% (12 of 33), 74% (26 of 35), 80% (20 of 23), and 0%, respectively. An open RCT [93] in El Salvador (*L. braziliensis braziliensis*) compared 10 mg/kg per day intravenous meglumine antimoniate once a day with 20 mg/kg oral allopurinol three times a day, both for 20 days. At 3 months the results showed healed lesions in 50% (8/16) of the patients and no healed lesions (one progressed to mucosal disease), respectively. A double-blind RCT [94] in Colombia (*L. panamensis*) compared 20 mg/kg per day intramuscular meglumine antimoniate for 20 days, three tablets of allopurinol 100 mg four times daily (20 mg/kg per day) for 28 days, and placebo. At 12 months the results showed cures in 92% (52 of 56), 32.7% (18 of 55), and 37% (17 of 46) of the patients, respectively.

We found two RCTs comparing oral allopurinol with stibogluconate. An open RCT [95] in Colombia (*L. braziliensis panamensis*) compared 20 mg/kg per day stibogluconate for 15 days with 20 mg/kg per day stibogluconate for 15 days plus oral allopurinol 20 mg/kg per day also for 15 days. At 12 months after therapy, 39% of the patients (19/49) were cured, 14% (7/49) relapsed, and the treatment failed in 43% (21/49), compared with cures in 71% (36/51), relapses in 27% (14/51), and treatment failure in 12% (6/51), respectively. An RCT [96] in Ecuador (*L. panamensis*) compared 20 mg/kg per day intramuscular stibogluconate for 20 days, oral allopurinol ribonucleoside (1500 mg q.i.d.) plus oral probenecid for 28 days, and no treatment. At 12 months the results in the stibogluconate group showed cures in 96.4% (27/28) of the patients. In the allopurinol group, 42.8% (9/21) of the patients were cured, and the treatment failed in 10 patients. In the untreated group, 75% (9/12) of the patients were cured and the treatment failed in three patients.

#### *Intramuscular pentamidine*

We found two RCTs comparing intramuscular pentamidine with antimonials. An open RCT [86] in Brazil (*L. braziliensis*) compared 10 mg/kg per day intramuscular meglumine for 20 days with 4 mg/kg per day intramuscular pentamidine, on alternative days, up to a

total of eight injections. At 3 years, only one patient in the meglumine group did not achieve a cure, and all of the other patients were cured. An open RCT [97] in Peru (*L. braziliensis*) compared 20 mg/kg per day intravenous meglumine antimoniate for 20 days with 2 mg/kg intramuscular pentamidine every other day, up to a total of seven injections. At 6 months, cures were observed in 78% (31 of 40) and 35% (14 of 40) of the patients, respectively.

### Oral miltefosine

An RCT [98] from Colombia and Guatemala (*L. braziliensis*, *L. panamensis*, and *L. mexicana*) compared oral miltefosine for 28 days with placebo. Six months after treatment the oral miltefosine had significantly higher cure rates than placebo in the Colombian site but not in the Guatemala site.

We found five RCTs comparing oral miltefosine with antimonials. An RCT [99] from Brazil (*L. braziliensis*) compared miltefosine with pentavalent antimony. Six months after treatment, in the intention-to-treat analyses, the definitive cure rate was 75% and 53.3%, respectively. Miltefosine was more effective than the antimonial in the 13–65-years-old age group compared with the 2–12-years-old group. An RCT [100] from Bolivia (*L. braziliensis*) compared oral miltefosine (2.5 mg/kg per day) for 28 days with intramuscular antimony (20 mg/kg per day) for 20 days. The cure rates with 6 months of follow-up were statistically similar: 36 of 41 evaluable miltefosine patients (88%) versus 15 of 16 (94%) evaluable antimony patients. However, antimony cured more rapidly. An RCT [101] from Brazil (*L. (Viannia) guyanensis*) compared oral miltefosine (2.5 mg/kg per day/28 days) in 60 patients with parenteral antimony (15–20 mg/kg per day/20 days) in 30 patients according to age groups: 2–12 years old and 13–65 years old. Cure rates at 6 months were 71.4% and 53.6% for miltefosine and the antimonial, respectively. There were no differences in cure rates between age groups within the same treatment arms. An RCT [102] conducted in Colombian army population (*L. (Viannia) braziliensis* or *L. (Viannia) panamensis*) compared 50 mg oral miltefosine three times per day for 28 days with 20 mg/kg of meglumine antimoniate per day for 20 days by intramuscular injection. The efficacy of miltefosine by protocol was 69.8% (85/122 patients) and 58.6% (85/145 patients) by intention to treat. For meglumine antimoniate, the efficacy by protocol was 85.1% (103/121 patients) and 72% (103/143 patients) by intention to treat. A single-blinded RCT [103] conducted in children from Colombia (*L. panamensis* and *L. guyanensis*) compared 20 mg/kg per day of intramuscular meglumine antimoniate for 20 days with oral miltefosine (1.8–2.5 mg/kg per day for 28 days). By intention-to-treat analysis, failure rate was 17.2% for miltefosine and 31% for meglumine antimoniate.

### Other treatments

We found very limited RCT evidence for the efficacy of other systemic treatments, such as immunotherapy with a parasite-derived antigen [104], associated vaccines [105], oral azytromycin [106], and adjuvant interferon gamma in intravenous meglumine antimoniate therapy [107].

We also found limited RCT evidence of lack of efficacy of oral mefloquine [108], early treatment versus deferred treatment of intestinal helminth infection on the clinical course of patients with CL treated with pentavalent antimony [109], and imiquimod in combination with pentavalent antimony [110].

### Drawbacks

The more frequent side effects of meglumine antimoniate are arthralgias, myalgias, asthenia, malaise, nausea, pruritus, headache,

and fever. There was no evidence of liver, cardiac, bone marrow, or kidney toxicity. The symptoms reported with stibogluconate include cases of pancreatitis, but no other significant side effects. Intramuscular paromomycin produced myalgias, anorexia, and asthenia. Even in some trials, oral miltefosine showed no side effects different from those of the placebo; adverse gastrointestinal events (vomiting, nausea, abdominal pain, and diarrhea) are generally associated with the use of miltefosine.

The only severe side effects attributable to allopurinol were headache and epigastric pain. Pentamidine produced cases of hypotension, hypoglycemia, headache, myalgias, anorexia, asthenia, and arthralgia.

### Comment

We found 32 RCTs that covered at least 11 different systemic treatments for American CL, which could be broadly categorized into eight main groups: intravenous/intramuscular meglumine antimoniate, intravenous/intramuscular stibogluconate, intravenous/intramuscular paromomycin, oral ketoconazole, oral allopurinol, intramuscular pentamidine, oral miltefosine, and other treatments.

The mainstay of systemic treatment for American CL is the use of pentavalent antimony compounds, which have been extensively used in practice and as controls in RCTs for newer treatments. In contrast to Old World CL, we found several RCTs comparing different antimonials. The results of some studies are difficult to interpret, as large numbers of patients were lost to follow-up.

### Implications for practice

Systemic therapy with intravenous or intramuscular pentavalent antimony compounds in American CL is regarded as being the first-line therapy, due to the progression to mucocutaneous disease in infections with *L. braziliensis*. There is moderate RCT evidence for the efficacy of these treatments.

There is moderate evidence for the efficacy of oral miltefosine. There is some RCT evidence for a lack of significant effects with oral ketoconazole (we found no RCTs for other antifungals), intramuscular pentamidine, and oral allopurinol.

### What is the randomized controlled trial evidence for local treatments in American cutaneous leishmaniasis?

#### Efficacy

##### Topical paromomycin/methylbenzothonium chloride

A double-blind RCT [111] in Guatemala (*L. braziliensis*) compared 15% paromomycin and 12% methylbenzothonium chloride twice a day for 20 days with placebo. A clinical response was observed after 12 months in 85.7% (31 of 35) and 39.4% (13 of 33) of patients, respectively. Another double-blind RCT [112] in Honduras (*L. mexicana* and *L. chagasi*) compared 15% paromomycin and 10% urea for 4 weeks with placebo. Complete cure occurred in 4.3% (1/23) and 3.3% (1/30) of participants in the respective groups 2.5 months (11 weeks) after treatment.

We found two RCTs comparing topical paromomycin/methylbenzothonium chloride with antimonials. A double-blind RCT [113] in Colombia (*L. braziliensis panamensis*) compared topical paromomycin/methylbenzothonium chloride twice a day for 10 days plus stibogluconate for 7 days, stibogluconate for 7 days, topical paromomycin/methylbenzothonium chloride twice a day for 10 days plus stibogluconate for 3 days, and injectable stibogluconate for 20 days. At 12 months the percentages of cure were 58%,

53%, 20%, and 84%, respectively. A double-blind RCT [114] in Ecuador (*L. viannia*) compared topical 15% paromomycin/12% methylbenzothonium chloride twice daily for 30 days, topical 15% paromomycin plus 10% urea twice daily for 30 days, and 20 mg/kg per day intramuscular meglumine antimoniate for 10 days. At 12 weeks after the start of treatment the percentages of cure were 57.5% (23 of 40), 52.5% (21 of 40), and 82.5% (33 of 40), respectively.

### Thermotherapy

We found two RCTs comparing thermotherapy with antimonials. An RCT [115] from Brazil (*L. (Viannia) braziliensis*) compared heat therapy given in a single session combined with intravascular meglumine antimoniate after day 28, with intravascular meglumine antimoniate, both for 20 consecutive days. Complete cure occurred in 5.9% (1/17) and 10% (2/20) of participants in the respective groups at the end of treatment. An RCT [116] from Guatemala (*L. braziliensis*, *L. mexicana*) applied three treatments of localized heat from a radiofrequency generator at 50°C for 30 s, at 7-day intervals compared with intramuscular meglumine antimoniate for 15 days. Complete cure 2 months after treatment occurred in 59% (13/22) and 73% (16/22) of participants in the respective groups.

### Topical imiquimod

We found two RCTs [117,118] from Peru (*L. braziliensis*, *L. peruviana*, *L. mexicana*, *L. amazonensis*) on adjuvant therapy with 5% imiquimod cream every other day for 20 days plus intramuscular meglumine antimoniate for 20 days and 7.5% imiquimod cream every other day for 20 days plus intravascular meglumine antimoniate for 20 days. There was no significant synergistic effect of topical 7.5% imiquimod combined with intravascular meglumine antimoniate in *L. braziliensis*, *L. amazonensis*, *L. mexicana*, or *L. peruviana* infections and no synergistic effect of topical 5% imiquimod combined with intramuscular meglumine antimoniate in *L. peruviana* and *L. braziliensis* infections. Topical 7.5% imiquimod had significantly lower cure rates than intravascular meglumine antimoniate in *L. braziliensis*, *L. amazonensis*, *L. mexicana*, and *L. peruviana*.

### Other treatments

We found limited RCT evidence for the efficacy of other treatments, such as WR279,396 (composed cream) [119] or adjuvant topical human granulocyte-macrophage colony-stimulating factor [120,121]. We also found limited RCT evidence of lack of efficacy of topical nitric oxide-releasing patches [122].

### Drawbacks

Side effects reported in topical paromomycin therapy included local pruritus, a burning sensation, local pain, and local edema. No significant adverse effect was seen or reported by heat therapy.

### Comment

We found 12 RCTs that covered at least six different local treatments for American CL, which could be broadly categorized into four main groups: topical paromomycin/methylbenzothonium chloride, thermotherapy, topical imiquimod, and other treatments.

### Implications for practice

Local therapy in American CL is an option only for patients who are not at risk of mucocutaneous disease and with early, not very inflamed lesions. However, there is no good RCT evidence to recommend any of the local treatments described. There is some RCT

evidence for the lack of efficacy of paromomycin or synergistic topical imiquimod. There was insufficient RCT evidence to make recommendations on thermotherapy.

### Key points

- In our search for the best available evidence on treatments for CL, we found 44 RCTs (21 different treatments) of local therapies and 29 RCTs (11 different treatments) of systemic therapies for Old World CL. For American CL, there were 32 RCTs (11 different treatments) of systemic therapies and 12 RCTs (six different treatments) of local therapies.
- There is a definite need to identify less-expensive, painless, and safer treatments for CL, but definitive recommendations are limited as there have been few rigorously designed randomized clinical trials.
- Varying susceptibility to the different species of *Leishmania* that occur in different geographical regions needs to be taken into account in the response to treatment.
- The development of drug resistance is a major concern when evaluating old trials.
- There is a need that lessons learned from previous research can better influence future clinical research in CL [123].

### Therapies for Old World cutaneous leishmaniasis

- An expectant approach may be appropriate in Old World endemic areas, in view of rapid spontaneous healing and the development of protective immunity in most cases.
- Pentavalent antimony compounds are considered to be the first-line therapy. Local treatment is used for patients with early, not highly inflamed, lesions on cosmetically or functionally important sites. Systemic therapy may be appropriate for patients with multiple or more complicated lesions.
- The range of affordable and painless treatment modalities includes oral drugs, but on the basis of the best present evidence the latter are unlikely to be beneficial. If well-tolerated oral agents are needed or preferred, then there is limited RCT evidence to support the use of oral itraconazole or fluconazole.

### Therapies for American cutaneous leishmaniasis

- Although systemic therapy with pentavalent antimony compounds may be expensive and their administration is associated with severe adverse effects, they are still the first-line drugs for American CL. Oral miltefosine can be used depending on the species causing the infection.

## Acknowledgments

Research for this chapter was supported in part by a grant from the Office of Control of Neglected Tropical Diseases (WHO/CDS/NTD/IDM), Communicable Diseases Cluster, World Health Organization.

Insect Research &amp; Development Limited, Cambridge, UK

**Background****Definition**

Scabies is an itchy immune hypersensitivity reaction to infestation of the skin by the mite *Sarcoptes scabiei*. Fertilized adult female mites burrow through the skin at the junction of the stratum corneum and the prickle cell layer, where they lay their eggs. Burrows are pushed out progressively towards the skin surface with the stratum corneum. Adult males and juvenile mites (larvae and nymphs) live mostly on the skin surface, but may make temporary burrows for molting from one development stage to another.

Infestation of immune-competent people is most common on the hands, digits and finger webs, and on the wrists. The flexor surfaces of the elbows, the axillae, ankles, buttocks, breasts, and male genitalia may also be infested. In the elderly, infants, and the immunocompromised, the infestation may be more diffuse, including the head and neck, and palms and soles.

**Incidence/prevalence**

We found no recent published data on the incidence or prevalence from any developed country. Scabies is a common public health problem in developing countries, where the prevalence may exceed 50% in some communities, and the prevalence has been estimated at 300 million cases worldwide [1]. Older studies have shown that the prevalence is highest in teenagers and schoolchildren [2–4]. However, the incidence has increased recently in the institutionalized elderly in nearly all countries. Historical data from Denmark show that epidemic cycles arise at 15–20-year intervals [2].

**Etiology/risk factors**

Transmission of scabies mites occurs during relatively prolonged skin–skin contact. The infection is most frequent in communities with long-term conditions of overcrowding, and is believed to increase following social disruption. Reduction of immune competence increases the risk of contracting infestation, with a concomitant risk of high mite numbers. We found no evidence that hygiene influences the risk, although good hygiene may ameliorate symptomatic presentation [5].

**Prognosis**

Scabies is not life threatening, but the severe, persistent itch and secondary infections may be debilitating and disfiguring. Long-term infestations are inherently immunodepressive and in susceptible people may lead to the development of a form of the disease in which large numbers of mites inhabit hyperkeratotic plaques. These shed skin plaques may be a source of reinfection and transmission [6]. In some circumstances, scabies infected with hemolytic streptococci may result in acute glomerulonephritis [5].

**Diagnosis**

A diagnosis of active infestation is confirmed only by finding mites, mite ova, or fecal pellets (scybala) (parasitological diagnosis). Dermoscopy and videodermoscopy may be more reliable methods for finding mites than skin scraping or other similar methods [7,8]. Mite burrows in the skin, the distribution of papular lesions, and bilateral itch not affecting the head, chest, or back are indicative (clinical diagnosis), as is clustering of cases of nocturnal pruritus associated with a rash in household contacts; but these findings are not confirmation of an active infestation. Nodular lesions around the axillae, navel, or on the penis or scrotum are pathognomonic, but may persist for months after cure.

**Aims of treatment**

The aim of treatment is to eliminate infestation by killing all mites and their eggs.

**Outcomes**

There are no established standard criteria for making a diagnosis or judging treatment success. Trials have used different methods, and in many cases the method was not stated. Treatment success should be given as the percentage of people completely cleared of scabies mites, ova, or fecal pellets in skin scrapings viewed under magnification. Clinical success includes elimination of papular and vesicular eruptions and pruritus. Ideally, outcomes should be assessed 28 days after the start of treatment, but interim assessments contribute to the clinical and parasitological picture. This allows time for lesions to heal, but assessment after 28 days risks

confounding of the result through reinfestation. If treatment fails, eggs hatch within 3 days, and emerging mites become mature 9–10 days later.

### Methods of search

- The initial search conducted for a systematic review compiled in 2010 [9] used the following primary sources: Cochrane Infectious Diseases Group Specialized Register; Medline, Embase, LLACS, IndMED, and grey literature.
- Medline update search for evidence-based dermatology, May 2012.
- Google Scholar search, June 2012.
- Manual searching of relevant journals.

### Context

Overall, studies in this therapeutic area are mostly either poorly designed or else poorly reported; in some cases it is difficult to determine just what the investigators did with their patients. Consequently, evaluation is often difficult and, because the studies are frequently too small to draw adequate conclusions unless there is a wide disparity in outcome between interventions, difficult to determine their practical value. Using the standard approach to clinical trial statistics, nearly all studies are too small to conclude equivalence, even with extremely wide, and therefore unacceptable, margins. Consequently, the only method of conventional analysis is to test for either noninferiority or more rarely superiority, and in most cases the studies are too small and too heterogeneous to conclude either. However, in many cases the authors' analyses are only given on the per-protocol (PP) compliant group of participants rather than the standard norm for clinical evaluation of the intention-to-treat (ITT) group. As a result, the reported outcome data are often optimistic given that several studies experienced a high level of drop-out or participants lost to follow-up.

A further significant drawback is that several studies attempted to compare too many therapeutic options concurrently. Nevertheless, many authors attempt to draw conclusions with a level of confidence not justified by the data. Such weaknesses are also compounded by poor reporting of factors such as use of retreatments, and in respect of the outcome criteria there are few consistencies

of approach to confirmation of initial infestation or adequate freedom from mites after treatment.

Although symptoms of scabies infestation may be relatively clear, especially in communities where the infestation may not be “modified” in presentation by earlier inadequate treatments, there is a need to demonstrate mites prior to initiating study treatment. This is especially important because most studies are conducted in resource-poor countries where the presentation of the disease may often be modified by secondary infection.

Since the last edition, no new or original developments have occurred in scabies treatment, and with resistance to all treatments a potential problem the dosing and application regimen may actually be more important than the material used.

### Questions

**How successful are topical treatments for scabies? For example, would a topical treatment be suitable for treating newly diagnosed scabies in a 16-year-old girl?**

**Insecticide-based pharmaceutical products**

#### Benefits

We found one systematic review (search date 2010) that examined 22 trials (18 compared drug treatments, one was placebo controlled, three compared treatment regimens, and one compared the drug vehicles). In each case, a single application of treatment was given, unless stated otherwise.

One study (150 adults and children) compared 5% permethrin cream with 10% crotamiton cream (a noninsecticide) and 1% lindane lotion [10]. It used clinical features as the measure of success (Figure 51.1). The results showed that, at 28 days, permethrin was slightly, but not significantly, more likely to cure patients receiving it (49 of 50; 98%), versus 44 of 50 (88%) with crotamiton. The same study also found that permethrin was significantly more effective than lindane, which cured only 12 of 50 (24%) people (relative risk, 4.08; 95% confidence interval [CI], 2.5–6.7) [10]. A single randomized controlled trial (RCT) comparing 5% permethrin cream with 10% crotamiton cream evaluated cure by elimination of parasites [11]. It found that permethrin was more effective after 14 and

(a)

(b)

**Figure 51.1** (a) Papules, pustules, and impetiginization in the vicinity of scabies burrows and (b) excoriated rash and papules on the wrists in simple scabies.

28 days. After 14 days, 33 of 47 people in the permethrin group (70%) and 41 of 47 in the crotamiton group (87%) still had lesions. At this point, 10 people in the crotamiton group were withdrawn from the study because their infestation was exacerbated. However, after 28 days, 42 of 47 people in the permethrin group (89%) were free from parasites, in comparison with 28 of 47 (60%) in the crotamiton group [11]. This study also recorded patients' subjective reports on the persistence of pruritus, which was found to be closely related to the effectiveness of the treatments.

Three trials compared the effect of 5% permethrin cream with that of 1% lindane lotion. A small study (including 46 patients) found that fewer people improved 14 days after using permethrin (13 of 23; 57%) in comparison with lindane (20 of 23; 87%;  $P < 0.02$ ), but there was a significantly better rate of cure, by parasitological examination, for permethrin at 28 days (21 of 23 vs 15 of 23;  $P < 0.025$ ) [12]. A larger trial (including 467 patients) did not identify parasites, but recorded a significant decrease in the number of lesions persisting in both groups after  $14 \pm 3$  days. At  $28 \pm 7$  days there was no significant difference in the success rates, with 181 of 199 (91%) cured using 5% permethrin cream, compared with 176 of 205 (86%) using 1% lindane lotion [13]. At the final assessment, significantly fewer of the patients in the permethrin group (27 of 194; 14%) had a persistent itch, in comparison with 49 of 197 (25%) in the lindane group ( $P = 0.007$ ) [13].

A medium-sized randomized, double-blind, crossover study (117 patients aged 6–64 years, plus contacts), conducted in Iran, investigated treatment with either 1% lindane cream or 5% permethrin cream [14]. Both treatments were applied for 12 h and repeated after 7 days. However, there were 11 drop-outs from the lindane group and seven from the permethrin group, not adequately explained by the authors. At 2 weeks, 44 of 52 (84.6%) had improved with permethrin and 23 of 47 (48.9%) with lindane. After 14 days, those considered still to be infected, using a mixture of parasitological and clinical criteria, were switched to the other treatment regimen. After 4 weeks, one person originally treated with permethrin and then retreated with lindane still showed severe pruritus. There were two irritation adverse events in the permethrin group and one in the lindane group.

We also found one previously unreviewed hospital-based RCT (80 patients aged 3–60 years), conducted in Pakistan, comparing 1% lindane cream with 5% permethrin cream [15]. No details of randomization method were given, and parasitological confirmation of infestation was made in 43 of the 80 (53.8%) participants. Products were administered at home, but no information on blinding was given. Follow-ups were made at 7, 14, and 28 days. Two patients lost to follow-up were not counted in the analyses by the authors. Confusingly, actual outcome data were not given, but it can easily be worked out that cure (not defined) for the ITT group was achieved for 35 of 40 people (87.5%) in the lindane group and also for 35 of 40 (87.5%) in the permethrin group. There were more adverse events, such as burning paresthesia and pruritus in those treated with permethrin, 10 of 40 people (25%) compared with six of 38 (16%) treated with lindane.

An observational multicenter study conducted in Germany (106 children and adults, aged 3 months–71 years) received a single application of 5% permethrin cream and were assessed after 14 and 28 days [16]. People who were not considered cured by dermatoscopy on day 14 were retreated, and 95.1% of the participants were diagnosed as being free from infection on day 28.

Two RCTs conducted in Italy evaluated synergized pyrethrins foam (0.16% pyrethrins, 1.65% piperonyl butoxide). In one study

(40 adults, 18–75 years) it was compared with 5% permethrin cream [17]. Both treatments were applied three times for 8 h on days 0, 1, and 14. Efficacy was assessed blindly on day 14 using a mixture of clinical criteria, but an itch index was used as the main criterion of success. A second assessment was made after 4 weeks. The foam was found to produce a significant difference ( $P = 0.013$ ) in reducing the number of lesions and the itch index at day 14 in comparison with permethrin, and the difference increased to  $P = 0.0001$  by the 4-week evaluation. The second RCT (including 240 convicted prisoners) compared three applications of synergized pyrethrins foam on consecutive days with five consecutive applications of benzyl benzoate lotion [18]. After 2 weeks, 90 of 120 of the patients in the group treated with pyrethrins (75%) were judged clinically cured, in comparison with 85 of 120 (71%) in the benzyl benzoate group. Those not considered cured were given another course of treatment with the same material, and after 4 weeks the cure rates were 95% and 91%, respectively. Those not considered cured still complained of itching. Burning and irritation due to treatment was significantly ( $P = 0.0001$ ) more common in the benzyl benzoate group, in which only 41% of participants showed good tolerability, compared with 95% in the pyrethrins group.

The systematic review identified no RCTs comparing 0.5% malathion. Anecdote suggests it is of diminishing effectiveness, and malathion products are no longer available in several countries where formerly used.

### Drawbacks

Only minor adverse effects have been reported for most insecticides. The exception is lindane, for which there are extensive reports of effects related to overdosing and absorption [19–21]. Because of recognized neurotoxicity, lindane is now restricted to second-tier use or is banned in most developed countries. However, it is still used in some resource-poor countries partly because alternatives are not readily available or are too expensive. Lindane passes transdermally during treatment and other exposures, and may be stored in fatty tissues and excreted in breast milk [22]. Acute exposure to lindane during scabies treatment has potentiated seizures in people on medication that reduces the seizure threshold [23,24]. Lindane appears to be contraindicated for those undergoing therapy for human immunodeficiency virus (HIV) infection [23], attention deficit hyperactivity disorder using amphetamine [24], and in those who suffer from epileptiform seizures. Concern has been expressed that lindane may be a risk factor for the triggering of seizures in epileptics, as it may alter liver cell function. Lindane does cause oxidative stress, but does not appear to modify liver microsomal function, and in experimental systems these effects were mitigated by prior treatment with phenobarbital [25,26]. Consequently, those being treated with barbiturates may be at lower risk of suffering side effects from lindane. However, it is not clear whether people receiving anticonvulsant drugs in general are at greater risk of having seizures if exposed to lindane.

Various studies have shown that the solvent vehicle plays an important role in the rate of transdermal absorption of lindane [27,28]. In addition, much of the drug can also be absorbed while the treatment is being washed off, because a depot of lindane builds up in the stratum corneum [28–30]. In many countries, and several of the studies reported here, scabicides are still applied after a hot bath, but the resultant peripheral vasodilation is likely to enhance transdermal absorption. A related increase in the passage of lindane through the dermis has been identified if soap and hot water are used to remove the acaricide at the end of the treatment process.

Absorption can be minimized if cool water alone is used to remove residues of lindane products before bathing [30]. An investigation of the absorption of permethrin and lindane through human cadaver skin *in vitro* found that lindane achieved a rate of  $2\mu\text{g}/(\text{h cm}^2)$  in less than 5 h, whereas the rate for permethrin was one-tenth of this after 10 h. However, fresh guinea-pig skin absorbed both at the same rate [31].

Most RCTs have reported no serious adverse events using these topical insecticide-based products. One RCT reported five serious adverse events, two possibly associated with permethrin (rash and diarrhea) and three possibly associated with lindane use (pruritic rash, papules, and diarrhea) [13]. Postmarketing surveillance of permethrin use in the USA from 1990 to 1995 found six adverse events per 100 000 units of product (equivalent to one central nervous system adverse event for each 500 000 units of permethrin used) [32]. Case series based on community intervention studies have reported a burning paresthesia as one of the most frequent adverse events following permethrin use, particularly in the immunodeficient [32,33]. A burning sensation was the most frequent adverse event, although not significantly so, in the largest RCT, with 23 events in 233 people following application of 5% permethrin, compared with 12 of 232 after 1% lindane lotion ( $P = 0.08$ ) [13], and one case report has suggested that use of even small doses of lindane ( $60\mu\text{g}$  on the body followed by  $40\mu\text{g}$  on the head 6 days later) may have contributed towards the death of a 91-year-old patient treated for scabies [34].

### Comment

Generally, it is believed that all mites and their eggs are killed soon after treatment, although eggshells and scybala may persist for some time in the stratum corneum. Confirmation of cure is therefore difficult, because mites may not be detectable in posttreatment skin scrapings. It is impossible, therefore, to determine success until sufficient time has passed to permit the various lesions resulting from the infestation to heal. Many people show considerable improvement after 14 days, but a definitive clinical cure cannot be concluded until about 28 days after treatment, when all lesions present at the time of treatment should either be healed or resolving, without new lesions developing.

Five of the RCTs were conducted in developing countries. One other study was divided between the USA and Mexico [13], and two were from Italy [17,18]. It is not known whether scabies mites may be more susceptible to treatment in communities in which treatments are not generally available, but it is likely that prior exposure to acaricidal chemicals may select for reduced sensitivity in mites in developed countries, and some cases of suspected resistance, particularly to lindane, have been recorded [32,35].

### Implications for clinical practice

The evidence indicates that permethrin is more effective than crotamiton and lindane and it has been associated with fewer side effects than lindane. However, the high cost of permethrin may limit its use in some communities. Permethrin is probably more likely to be effective with one application than are other insecticides, but a second treatment may be necessary for all [36].

### Noninsecticide-based acaricides

#### Benefits

Randomized studies comparing the noninsecticide antiscabies agent crotamiton with insecticide-based treatments were described above.

We found one trial (158 adults and children) comparing 25% benzyl benzoate with sulfur ointment (concentration of sulfur not given) in a community study in India [37]. In this study, patients were first scrubbed in a bath; the treatments were then applied three times in 24 h (morning, night, and next morning). Assessments were made at approximately 5-day intervals. No significant difference was found between the treatments with regard to improvement of the lesions at 9–10 days – benzyl benzoate 68 of 89 (76%) versus 45 of 69 (65%) with sulfur. If lesions remained at this time, the patients were treated again, so that by 14–15 days there was improvement of symptoms in 81 of 89 patients (91%) in the benzyl benzoate group, in comparison with 67 of 69 (97%) for sulfur, which was also not significantly different. Another RCT conducted in Thailand (100 children aged 6 months–13 years) compared 10% sulfur ointment with 0.3% hexachlorocyclohexane (lindane) gel [38]. After 4 weeks of treatment, there was no significant difference between the treatments whether they were assessed using clinical signs (92% success for sulfur compared with 91% for lindane) or by parasitological findings (83% compared with 84% cure). However, the authors reported a significant difference ( $P < 0.05$ ) in adverse effects due to the foul odor following sulfur treatment.

Noncontrolled studies and case studies have indicated variable effectiveness for both benzyl benzoate (20% emulsion [39], 25% cream [40]) and sulfur ointment (5% [41], 6% [42], 10% [39,42], 2–8% [38]). The activity of these acaricides is related to the concentration of active drug in the vehicle and the number of times they are applied. In general, benzyl benzoate appears to require a minimum of two applications, and sulfur may require several applications over 1 week or longer [43,44].

We found a single RCT evaluated by the systematic review comparing pork fat containing 1% salicylic acid and cold cream as ointment vehicles for the delivery of sulfur [45]. The numbers in this study were small (51 confirmed cases), and differences in efficacy could have been due to chance effects. Every participant applied the sulfur ointment on three consecutive nights and then again 3 days later. Evaluations were made on the tenth day after the last treatment. This study is more relevant for the side effects observed, described below.

A recent RCT (110 children and adults, of whom 13 were drop-outs of some kind, not explained) compared three treatment regimens using either 8% (for children younger than 12) or 10% (for those over 12) sulfur ointment [46]. The method of randomization and the justification for using different concentrations were also not explained. Treatment was applied either once for 24 h or three times either on successive nights or on successive days, with bathing between treatments. Follow-ups were made at 14 and 28 days. Because original randomization allocations were not given, it is only possible to report the PP outcomes, which were cure (undefined) in only 14 of 33 people (42.4%) receiving a single application of sulfur compared with 29 of 32 (90.6%) applying the preparation on three successive nights or 31 of 32 (96.9%) applying on three successive days. The difference between a single and three applications was highly significant ( $P < 0.0005$ ), although the authors suggested significance of as much as  $P = 0.00000011$ . In this study, dermatitis side effects induced by the sulfur were reported in four cases (12.1%) following the single treatment regimen but eight (25%) and 11 (34.4%) cases following the two three-treatment regimens [46].

We found one study claiming randomization, without giving the method, that compared two products based on Nigerian plant extracts [47]. The authors state that they were “produced from

herbs that have acclaimed medicinal value.” However, the ingredient lists of the two preparations show nothing more than palm oil and shea butter as included plant derivatives. This study included scabies as one arm of an investigation of the two products against a variety of infections and involved 64 patients. The mean period of use to “clinical success” was 6.1 weeks using either Toto ointment, with 41/47 (87.2%), Toto soap 5/5 (100%), or both products together 12/12 (100%) success treatments.

Other noninsecticide active materials have only been described in nonrandomized studies and case series. One nonrandomized study comparing 5% sulfur ointment, 1% lindane cream, 25% benzyl benzoate cream, 10% crothamiton lotion, and 0.2% nitrofurazone in a water-soluble ointment found that nitrofurazone was the least effective, with a 70% cure rate [40]. A case series of 20 patients using the same nitrofurazone ointment produced “complete clinical cure” in 80% of cases [48].

Monosulfiram (sulfiram) is now mainly used only as a soap in resource-poor countries. Most studies are of poor quality and more than 50 years old, and more recent case studies show a high incidence of side effects (see Drawbacks section). Thiabendazole has been used as a 5% and a 10% cream applied over several days. In one case series, five of 19 patients (26%) were still infested after 5% cream was used twice daily for 5 days. The remaining patients were cured after a further 5 days of treatment [49]. Another case series, in which 10% cream was used, achieved an 80% success rate after 5 days [50].

### Drawbacks

Generally, studies have reported “only minor adverse reactions” for noninsecticide treatments for scabies. Most of these have been related to skin irritation or dermatitis, often following repeated or multiple applications of the formulation. The RCTs comparing vehicles or treatment regimens for sulfur ointment [45,46] did not provide adequate data for a full analysis of effects. Side effects were reported in patients and close contacts within 6 days of first being treated with either cold cream or pork fat with 1% salicylic acid: pruritus (31% vs 60%), xerosis (24% vs 34%), burning sensation (12% vs 17%), erythema (10% vs 2%), and keratosis (2% vs 15%) [45]. Where sulfur is used in developed countries, it is normally applied in petroleum jelly, and similar skin reactions have been reported as side effects in trials, case studies, and series [44,46,51]. Similar irritant reactions occur with repeat treatments using benzyl benzoate, particularly if naturally derived rather than synthetic material is used [44,52]. In one RCT, approximately 25% of people reported an increase in pruritus and dermatitis after treatment with two applications of 10% benzyl benzoate [53].

Monosulfiram in an alcohol vehicle has been associated with a systemic adverse event in a number of case reports in which the patients developed dermal edema, flushing, sweating, and tachycardia, especially after ingesting alcohol within 24 h of treatment [54–56]. This reaction occurs because monosulfiram is chemically related to disulfiram, used in the treatment of alcoholism (Antabuse). We could find no similar reports related to use of monosulfiram soaps.

Multiple applications of crothamiton can result in dermatitis, and there is one report of a suspected link with methemoglobinemia [20,44,57].

### Comments

Most studies in this group are not comparable owing to differences in the formulations used, in the concentrations of the active substances, and in the duration or number of applications. Evidence

for activity is limited in each case, and it is possible that some of the effectiveness is partially related to a physical effect – for example, sulfur in a heavy greasy base may physically trap and subsequently remove developmental stages of the mite from the skin surface, as would repeated use of ointment containing palm oil and shea butter. The mode of action of crothamiton is not understood, and there is doubt about both its acaricidal and antipruritic activities. Similar questions may apply to all of the noninsecticide-based treatments. The fact that these treatments are inexpensive means that they are more likely to be used in resource-poor and developing countries, where source materials may be less well characterized. Most of these compounds have been in use for around 50 years, and there is suspicion that resistance is developing in some areas [20].

### Implications for clinical practice

All of these products are likely to require two to four applications and are not particularly cosmetic. They may, therefore, suffer from compliance problems – for example, sulfur has a particularly unpleasant odor. However, the low cost and relative safety, apart from skin irritancy, make noninsecticide-based acaricides attractive alternatives to insecticide-based products where mites may have developed resistance or if cost is an issue.

### How successful are oral treatments for scabies? Would an oral treatment be suitable for treating an 82-year-old resident in a nursing home?

#### Orally administered treatments

##### Benefits

We found one systematic review examining eight RCTs of variable size and quality, one of which had inadequate follow-up. A placebo-controlled RCT (including 55 adults and children) found that significantly more people (23 of 29; 79%) treated with ivermectin, 200 µg/kg, were free from symptoms at 7 days, in comparison with two of 26 (8%) treated with placebo. The code was then broken and the controls and all patients who had not improved received ivermectin [58]. A comparative RCT (44 people) found no significant difference at 30 days in improvement of lesions between ivermectin 100 µg/kg (16 of 23; 70%) and benzyl benzoate 10%, applied twice over 2 days (10 of 21; 48%) [53].

It also evaluated one RCT (including 85 patients) comparing ivermectin 200 µg/kg with 5% permethrin cream, evaluated at 1, 2, 4, and 8 weeks [59]. In this study, a single dose of ivermectin relieved symptoms in 28 of 40 patients (70%), which was significantly fewer than permethrin (44 of 45; 98%). However, when a second dose of treatment was given after 2 weeks, there was no significant difference in the improvement rate between the ivermectin group (38 of 40; 95%) and the permethrin group, in which everyone was cured.

We found three new RCT reports published since the systematic review that compared ivermectin with permethrin. The first, from Pakistan (100 patients, with 14 lost to follow-up), compared a single dose of ivermectin 200 µg/kg with one 12-h application of 5% permethrin cream [60]. Parasitological examinations were performed and photographs taken at the commencement and after 4 weeks, with an interim examination at 2 weeks. At 2 weeks, 24/44 (54.5%) in the ivermectin group appeared cured, as did 20/42 (47.6%) treated with permethrin. Those not cured were treated again, so that at the fourth week 35/44 (79.5%) receiving ivermectin were cured compared with 37/42 (88.1%) receiving permethrin, showing no significant difference whether by ITT or PP analysis. There was

a significant difference in adverse events, with one patient having burning paresthesia in the permethrin group but seven events in the ivermectin group (four severe itch, three secondary bacterial infection, one headache) ( $P = 0.05$ ).

Another study in Pakistan (120 patients, all of whom completed the study) compared 200 µg/kg with 5% permethrin lotion (details of formulation not given) applied once for 10–12 h [61]. Infestation was confirmed by microscopy in about one-third of patients, and photographs were taken on days 0 and 14. Follow-up examinations were at 7 and 14 days. Efficacy was estimated on a graded scale, but cure at 7 days was reported as 41/60 (68.3%) for ivermectin and 44/60 (73.4% [*sic*]) for permethrin. However, by 14 days the cure rate was reported as 40/60 (66.7%) for both treatments. In addition to “cure,” the treatments were reported as “very effective” in a further 25% for permethrin and 20% for ivermectin.

A double-blind RCT from India (120 patients, three lost to follow-up) also compared ivermectin (two treatment regimens) with permethrin [62]. More than 70% of participants had infestation confirmed parasitologically by skin scraping and were followed up 7, 14, and 28 days after initial treatment. Treatments were: (i) ivermectin 200 µg/kg given once on day 1, together with a placebo cream, followed by placebo tablets (vitamin B-complex) on day 15; (ii) ivermectin 200 µg/kg given twice on days 1 and 15, with placebo cream on day 1; (iii) 5% permethrin cream on day 1, with placebo tablets on days 1 and 15. Cure was defined as 50% or more improvement in number of lesions, pruritus, and negative microscopy. Outcomes at 7, 14, and 28 days were 29/40 (72.5%), 38/40 (95%), and 36/40 (90%), respectively, for the single-dose ivermectin regimen and 29/40 (72.5%), 36/39 (92.3%), and 36/39 (92.3% PP, 90% ITT), respectively, for the double-dose ivermectin regimen. In contrast, the permethrin treatment gave a more rapid response, with 37/40 (92.5%) at 7 days, followed by 37/38 (97.4%) and 38/38 (100% PP, 95% ITT) after 28 days. These differences were not statistically significant [62].

A more complex RCT from India (103 patients, 23 lost to follow-up) divided between three treatments: ivermectin 200 µg/kg in a single dose, 25% benzyl benzoate lotion applied twice overnight on two consecutive nights, and 5% permethrin cream applied once [63]. Follow-ups were made at 7 and 14 days after treatment. If patients were not cured at 7 days they were retreated, but the results at 7 days were not reported. At 2 weeks posttreatment only PP analyses were given for the outcomes of 27/27 (100% PP, 79.4% ITT) cured (defined as no new lesions) for ivermectin, 27/28 (96.4% PP, 79.4% ITT) for permethrin, and 23/25 (92% PP, 65.7% ITT) for benzyl benzoate. The majority of the report was actually devoted to the economics of treatment, which concluded that, despite its low efficacy, benzyl benzoate was the most cost-effective product.

A similarly complex RCT from Senegal (181 patients, 22 lost to follow-up) used a skewed randomization to compare a single dose of ivermectin 150–200 µg/kg, taken on an empty stomach (68 patients), with a single 24-h application of benzyl benzoate 12.5% (65 patients), or two applications of benzyl benzoate separated by 24 h (48 patients) [64]. Follow-ups were conducted at 7, 14, and 28 days primarily using clinical diagnostic criteria. A retreatment at 7 days was considered necessary for seven patients in the ivermectin group, but none in either of the benzyl benzoate groups required a second treatment. Analyses were given ITT at 14 and 28 days as follows: ivermectin cure rates 16/54 (24.6%) and 28/65 (43.1%); benzyl benzoate applied once gave 37/65 (56.9%) at 14 days and 52/68 (76.5%) at 28 days, whereas respective outcomes for the double treatment with benzyl benzoate were 33/48 (68.8%) and

46/48 (95.8%). Both benzyl benzoate outcomes were highly significantly ( $P = 0.00008$  and  $P < 10^{-5}$ ) better than ivermectin. In this study, 30 patients experienced a dermatitis reaction to benzyl benzoate and seven had either abdominal pain (five) or diarrhea (two) following ivermectin treatment. This study was planned to recruit 400 patients, but because ivermectin proved so ineffective and showed a significantly higher risk of superinfection the study was terminated early for ethical reasons [64].

A relatively small RCT (53 patients, 43 of whom completed the study) found that ivermectin 150–200 µg/kg was statistically equivalent to 1% lindane lotion [65]. After 15 days, 14 of 19 patients (74%) had improved with ivermectin, in comparison with 13 of 24 (46%) treated with lindane. At 29 days, all but one of the remaining accessible patients in each group were cured – 18 of 19 (95%) with ivermectin versus 23 of 24 (96%) with lindane.

A large RCT conducted in India (including 200 patients) compared ivermectin 200 µg/kg with 1% lindane lotion applied overnight [66]. Assessments were made at 48 h, 2 weeks, and 4 weeks after treatment. After 4 weeks, 82.6% of the ivermectin group showed marked improvement, based on a clinical assessment, in comparison with 44.4% of those treated with lindane. The only adverse event of note was a severe headache in one person treated using ivermectin. Another RCT (110 children aged 6 months–14 years at the start of the study) conducted in Vanuatu compared a single dose of oral ivermectin 200 µg/kg with one application of 10% benzyl benzoate emulsion [67]. After 3 weeks, an assessment was made using clinical diagnostic criteria, in which 24 of 43 of the ivermectin-treated patients (54%) were considered cured, in comparison with 19 of 37 of those receiving benzyl benzoate (51%). This difference was not significant, but benzyl benzoate was significantly more likely to induce adverse skin reactions ( $P = 0.004$ ; odds ratio, 6.4, 95% CI, 1.6–25.0). However, this study suffered from a drop-out rate of 27% (30 of 110), which was not adequately explained by the authors.

An observational cohort study (six families, 12 adults and 20 children aged 1–10 years) used a 1% solution of ivermectin in propylene glycol to give a total dose of 400 µg/kg, applied twice with an interval of 1 week [68]. Evaluation was made on the basis of clinical evidence at 2, 4, and 6 weeks. All of the patients were cured without side effects or relapse.

### Drawbacks

Most of the RCTs were too small or too complex to provide adequate safety data for the use of ivermectin against scabies, particularly in children. What comment there is about adverse experiences is often inadequate, as most authors who report adverse events at all generalize comments to stating that adverse experiences “were mild” or treatments were “well tolerated”; such comments are wholly meaningless and no guide to what might be expected in clinical use. Ivermectin has been used extensively in community control programs for onchocerciasis and filariasis, and there have been few reports of serious adverse events [69,70]. There has been one report of a significant increase in the mortality rate in a psychogeriatric unit – 15 of 42 (36%;  $P = 0.001$ ) within 6 months of ivermectin use, in comparison with controls in the same care facility over a 3-year period [71]. However, each resident in the unit had previously received several applications of other scabies treatments, including lindane and permethrin. Use of ivermectin in the elderly in other countries has not resulted in any similar increase in mortality [72,73].

### Comment

Ivermectin has not yet been widely licensed for use against scabies. However, its use on a named-patient basis has become widespread as a component of treatment for hyperkeratotic scabies, in which it is often difficult to kill all the mites due to the limited penetration of the plaques (Figure 51.2) by topical acaricides. In this condition, ivermectin can reach trophic mites by incorporation into the living cell layer on which the mites feed. However, ivermectin is unlikely to have any direct effect on mite eggs, and failures of treatment have been reported unless either dosing is repeated or a topical scabicide is used concurrently [74–76]. So far, no proper dosing studies using ivermectin have been performed, and the relative underdosing using both ivermectin and benzyl benzoate in one study indicates how important a contribution to knowledge this would be [53]. Apart from drug dose level, timing of dosing with ivermectin is no doubt important in relation to efficacy. Of the newer studies, three gave no information on timing [60,61,63], one advised “before breakfast” [62], and one advised “on an empty stomach” [64], which would potentially have reduced the effective dose levels because the manufacturer suggests bioavailability is improved if the drug is taken with fatty food [76]. Furthermore, the borderline dose level of 150–200 µg/kg used in the Dakar study [64], combined with taking on an empty stomach, could have reduced uptake levels below an effectiveness threshold. However, it should also be noted that ivermectin had been used in Senegal in mass treatment programs for elimination of onchocerciasis for nearly 20 years prior to this evaluation of the drug for scabies, which could have selected for resistance in the mites. Similar repeated exposures using ivermectin in northern Australia for scabies control has resulted in selection of resistance there, and resistance to ivermectin as well as permethrin, the most widely used acaricide, will no doubt spread [77,78].

### Implications for clinical practice

A reliable and safe oral treatment is an attractive option for dosing and compliance with scabies treatment. However, ivermectin has still not yet been evaluated sufficiently to determine the most appropriate dosing regimen. It is likely it will never replace topical treatments, but used correctly it can be a useful adjunct to conventional treatment approaches.

### Additional comment

The evidence for the effectiveness of all scabies treatments is still largely rudimentary, and the majority of studies have employed inadequate criteria for diagnosis and evaluation of efficacy. It is almost impossible to compare most studies, even when they are sponsored by the same organization, as almost every trial employs a different protocol and set of criteria for making the initial diagnosis, follow-up diagnoses, treatment regimen, and evaluation of success. The majority of studies have been conducted in developing countries, where scabies is not only more highly endemic than in western Europe or North America, but in many cases is also less likely to have been subjected to any form of therapeutic intervention. As a result, treatments should exhibit exemplary activity against these chemically naive mites. However, the most worrying aspect of reading the study reports is that, even in circumstances in which resistance to treatment cannot be an issue, the treatments of all types exhibit a disturbing lack of efficacy in the absence of retreatment and in some cases multiple retreatments. What evidence exists indicates that none of the topical products is reliable with a single application, and this picture may be further confused by the possibility that resistance to conventional neurotoxic compounds may have developed in some communities. The limited evidence available for oral ivermectin is far from the aspirations expressed by those dealing with problems of long-term infestation, and there is now evidence that in some regions the mites are no longer fully sensitive to ivermectin and in many cases are developing tolerance already. Consequently, further investigation is required for this and other neurotoxic insecticide treatments – first, to determine adequate drug regimens and reliable methods of evaluating them and, second, to confirm the susceptibility of the mites to those treatment compounds in all geographic zones.

### Key points

- Permethrin is probably effective in scabies treatment. Lindane has been withdrawn from most markets and has a higher potential for toxicity. Synergized pyrethrins may be effective, but more evidence is required and there is insufficient evidence that malathion shows activity.
- Crotamiton, benzyl benzoate, and sulfur show insufficient evidence of efficacy, as do nitrofurazone, monosulfiram, and thiabendazole.
- There is currently insufficient evidence of the effectiveness of ivermectin. Most studies have been small trials and larger studies have suffered high drop-out rates. Case studies indicate that ivermectin may be effective if used with a topical agent. A proper dose regimen evaluation is required. However, there is now evidence of resistance in some localities.

## CHAPTER 52

# Head lice

Ian F. Burgess and Ciara S. Casey

Insect Research & Development Limited, Cambridge, UK

## Background

### Definition

Head lice (*Pediculus capitis*) are blood-feeding insects that are obligate ectoparasites of socially active humans. All stages of the life cycle infest the scalp, where the adult insects attach their eggs to the hair shafts. The juvenile forms (nymphs) are essentially miniature versions of adults, and there is no distinct larval stage.

### Incidence/prevalence

We found no data on the incidence and few recent published prevalence data from developed countries. Anecdote suggests that the prevalence increased in most communities in Europe, the USA, and other developed countries during the 1990s. One study in Belgium found a prevalence of up to 19.5% in some schools, and in a follow-up investigation of 6169 children (2.5–12 years) there was an overall prevalence of 8.9% [1,2]. A more recent study in Norway, where overall prevalence was low (1.63%), suggested that population density of the community and the age of the eldest child attending elementary school were the most significant factors influencing risk of infestation [3]. In one study, low socioeconomic status was a significant risk for the presence of infestation and an inability to treat these effectively [2].

### Etiology/risk factors

Observational studies indicate that infestations occur most frequently in schoolchildren, although there is no evidence of a link with school attendance. We found no evidence that either hygiene or hairstyle influences the risk, or that lice prefer clean hair to dirty hair.

### Prognosis

This infestation is essentially harmless. However, the stigma associated with head lice and the psychological trauma experienced by some people in their efforts to eliminate the infection greatly outweigh the physical impact of the infestation. Sensitization reactions to louse saliva and feces may cause local irritation and erythema. Secondary infection of scratches may occur. Lice have been identified as primary mechanical vectors of scalp pyoderma caused by streptococci and staphylococci usually found on the skin [4].

### Diagnosis

Only finding living lice on the scalp can confirm a diagnosis of active infestation (Figure 52.1). Eggs glued to hairs, whether hatched (nits) or unhatched, are not proof of active infection, because dead eggs may appear viable for weeks. Itching, resulting from multiple bites, is not diagnostic, but may increase the index of suspicion. Combing is a more effective diagnostic method than visual inspection of the hair [5–8].

### Aims of treatment

The aim of treatment is to eliminate infestation by killing or removing all head lice and preventing their eggs from hatching.

### Outcomes

Treatment success is given as the percentage of people completely cleared of head lice. There are no standard criteria for judging treatment success, although guidelines have recently been published [9]. Many trials have used different methods, and often the method was not stated. Few studies are pragmatic.

### Method of search

- The Cochrane Infectious Diseases Group at the Liverpool School of Tropical Medicine performed the initial search for a systematic review compiled in July 1998, updated in February 2001 and July 2006; search date March 2006; primary sources: Cochrane Central Register of Controlled Trials, Medline, Embase, Bath Information and Data Services (BIDS SC), BioScience Information Service (BIOSIS), and Toxicology Literature Online (Toxline).
- Medline update search for evidence-based dermatology, May 2012.
- Google Scholar search, June 2012.
- Manual searching of relevant journals.

### Context

Selection of studies for inclusion is based primarily on their status as randomized, controlled, trials with adequate reporting, randomization, and follow-up. However, an additional factor, not normally taken into account, is the context and timing of the studies. For example, does a study conducted in a closed environment such as

Figure 52.1 Head lice are difficult to see against human skin.

a boarding school or an isolated island community have the same weight as a study conducted in the wider community where participants are likely to have multiple encounters with other potentially infested people during the course of the study? One way in which investigators have attempted to address this question is to report the background prevalence of infestation in the community. However, as far as can be determined, these data have never been used in any informative way to evaluate the outcome data, so reporting of prevalence seems to exist in a contextual vacuum.

The second factor that must be considered is the age of the study. Does the outcome of an investigation performed 30 years ago, using a newly introduced active substance, carry the same weight now as a study performed within the last 2–3 years? Obviously the value depends upon where the studies were conducted and how much the particular material has been used in the geographical region in the past. This is particularly important when considering the value of studies sponsored by the pharmaceutical industry because they are more likely to compare a “new” material with something that may have been used for many years and can thereby demonstrate superiority because the old material is now affected by resistance or vigor tolerance. This practice is not necessarily an indication of bias because there may be good therapeutic reasons for demonstrating that an established treatment favored as an “old friend” by prescribers should no longer be employed. However, the justification for using such a product comparison should be considered.

## Questions

### How successful are treatments for head lice?

#### Case scenario 52.1

A 10-year-old girl with shoulder-length hair is diagnosed with head louse infestation. How easy would it be to treat her?

#### Insecticide-based pharmaceutical products

**Efficacy** We found two systematic reviews [10,11]. The first (search date March 1995; seven randomized controlled trials, 1808 people), of 11 insecticide products, included lindane, carbaryl, malathion, permethrin, and other pyrethroids in various vehicles [11]. Two randomized controlled trials (RCTs) were selected as showing that only permethrin produced clinically significant differences in the rate of treatment success. Both compared lindane (1% shampoo)

with permethrin (1% crème rinse) [12,13]. In that analysis, permethrin was found to be more effective than lindane.

The first Cochrane systematic review (search date May 1998, updated February 2001) set stricter criteria for RCTs and rejected all but four trials [10]. It initially excluded both studies on which the earlier review was based. The most recent update of Cochrane (July 2006, now withdrawn), in attempting to address criticisms of the 2001 publication, evaluated a wider range of studies in greater detail. No clear therapeutic guidelines were obtained from the analyses, as it was impossible to draw up-to-date conclusions from the widely differing results obtained using different formulations of the same materials, different treatment regimens, and different assessment criteria, at different times, especially where resistance to insecticides has had an impact on some of the better-designed trials. A new Cochrane review is at the protocol stage [14].

One RCT (193 schoolchildren) compared malathion (0.5% alcoholic lotion) with *d*-phenothrin (0.3% lotion – no longer available in many countries), both applied for 8 h or overnight. One day after treatment, fewer people treated with malathion had lice – eight of 95 (8%) versus 59 of 98 (60%) treated with phenothrin. This difference had increased by day 7 – six of 95 (6%) versus 60 of 98 (61%). However, some children not free from lice on day 1 had become louse free by day 7 in both groups, suggesting that some parental intervention had influenced the results, but no further follow-ups were performed [15]. One RCT (66 people) compared 0.5% malathion (alcoholic lotion applied for 20 min) with 1% permethrin (crème rinse applied for 10 min). One application was used, but a second treatment was given if lice were found after 7 days. At day 7, 33 of 41 people (80%) treated with malathion were louse-free, as were 13 of 22 (59%) treated with permethrin. After the second treatment, the overall cure rate at day 14 was 40 of 41 for malathion (98%) and 15 of 22 (68%) for permethrin [16].

We found one report describing two multicenter, double-blind RCTs comparing effectiveness of 0.5% ivermectin lotion with the product vehicle. Data from the two studies were combined for the effectiveness analysis of the 289 enrolled youngest family members. A further 781 family members took part in a safety analysis. A single 10 min treatment evaluated 14 days later showed 104 children from 141 (73.8%) were louse free throughout the period after treatment compared with 26 of the 148 (17.6%) receiving the vehicle placebo [17].

We found another report of two multicenter RCTs that compared 0.9% spinosad crème rinse, without nit combing, and 1% permethrin crème rinse plus nit combing. Both products were applied for 10 min, with a repeat after 7 days if lice were present. In the first RCT, households were randomized and all members of the household treated. Ninety-one households (243 patients) were allocated spinosad and 89 households (256 patients) received permethrin. In the second RCT, 83 households (203 people) were treated with spinosad or 84 households (214 people) were given permethrin. Analysis of outcome was measured in the youngest household member (180 children in the first RCT and 167 in the second RCT) who were lice free at 14 days after the last treatment. Absolute outcomes were not clear because they were given as percentages, with 84.6% success for spinosad and 44.9% for permethrin in the first study and 86.7% and 42.9% respectively in the second trial [18].

**Drawbacks** Only minor adverse effects have been reported for most insecticides. The exception is lindane, which has been withdrawn from use in nearly all developed countries and for which

there are extensive reports of effects related to overdosing (treatment of scabies), and absorption (treatment of head lice). Lindane passes transdermally during treatment of head lice [19], and a specific review has now summarized all case histories of adverse events resulting from its use in this application [20].

We found no confirmed reports of adverse effects from therapeutic exposure to the organophosphorus compound malathion. A randomized, open, volunteer study (32 people) examined transdermal absorption of malathion from four head louse treatment products formerly available in the UK [21]. Urinalysis for malathion metabolites found that 0.2–3.2% of the applied dose was eliminated in urine, before decreasing to baseline values by 96 h. Erythrocyte cholinesterase levels were clinically unaffected, irrespective of dose or whether the skin was excoriated.

Pyrethroid insecticides are listed as contraindicated for people with ragweed allergy, but we found only one report of an anaphylactoid reaction to a head louse treatment product [22].

**Comments** Follow-up for 7 days is inadequate, because louse eggs normally take at least 7 days to hatch. A second application of insecticide should be given 7–10 days after the first treatment. The primary end point of a study is absence of infestation at least 14 days after first treatment.

No RCT has yet evaluated the effect of formulation vehicle activity. Studies *in vitro* suggest that excipients of products (e.g., terpenoids and solvents) may have contributed significantly to pediculicide activity, in some cases more than the insecticide itself [23].

Resistance to one or more insecticides has now been identified in most developed countries. There are no data on the prevalence of resistance. However, resistance to pyrethroids (permethrin, *d*-phenothrin, and natural pyrethrum) is widespread in Europe, North America, and Australia, and malathion resistance is present in Europe and Australia [24–29].

**Implications for practice** Evidence for efficacy of any older insecticide-based pediculicide is now extremely limited. Early commercial support for permethrin produced a greater body of evidence of its efficacy. However, all older insecticides still in use are affected by resistance, which varies considerably both within and between countries. Available data are insufficient to judge this factor other than on a case-by-case basis, but more recent studies conducted to evaluate noninsecticide products and using insecticides as comparators are probably a good indication of the impact of resistance on communities. The newer insecticides ivermectin and spinosad are not affected by resistance, and are still relatively less widely used than older materials, which would reduce the risk. However, it is possible that resistance will appear in head lice in the future, and users should be conscious of this possibility. In cases of treatment failure, where resistance is indicated by finding all stages of lice soon after treatment, an alternative treatment approach – for example, physical removal, physically disrupting insecticide, or herbal material – would be more appropriate.

#### **Physically disrupting insecticides**

**Efficacy** We found one RCT (253 children and adults) conducted in the UK comparing 4% dimeticone lotion (4% high molecular weight dimeticone in a cyclomethicone solvent) with 0.5% *d*-phenothrin aqueous liquid (no longer available in any country). Both products were applied overnight using two applications 7 days apart, with follow-ups on days 2, 6, 9, and 14. At 14 days, no sig-

nificant difference was found between the numbers of individuals free of lice with phenothrin liquid (94/125, 75%) or with dimeticone lotion (89/127, 70%) [30].

A second RCT (58 children and 15 adults) in the UK compared the same 4% dimeticone lotion with 0.5% malathion aqueous emulsion (no longer available in any country) [31]. In this study also, followed up on four occasions, both products were applied overnight and reapplied after 7 days. Cure of infestation was defined as no evidence of head lice after the second treatment, and particularly by day 14. Some people were found free from lice but later were reinfested. Worst case, intention-to-treat (ITT), analysis found dimeticone was significantly more effective than malathion, with 30 of 43 (69.8%) participants cured using dimeticone compared with 10 from 30 (33.3%) using malathion ( $P < 0.01$ , relative risk [RR], 2.09; 95% confidence interval [CI], 1.21–3.60). Per-protocol analysis showed cure rates of 30/39 (76.9%) and 10/29 (34.5%) respectively.

An RCT conducted in Turkey (72 school children) compared 4% dimeticone lotion with an alternative formulation, both products applied overnight on two occasions a week apart [32]. The ITT analysis showed 35 of 36 (patients treated with the commercial lotion had no lice after the second treatment but there were two protocol violators, giving 91.7% treatment success. The alternative product gave 30/36 (83.3%) treatment success, a difference of 8.4% (95% CI, –9.8 to +26.2%). The cure rates per-protocol were 33/34 (97.1%) and 30/35 (85.7%) respectively.

We also found an RCT conducted in Brazil (145 children 5–15 years) comparing a different dimeticone lotion (92% mixture of low molecular weight dimeticones with triglycerides, jojoba wax, and terpenoids) with 1% permethrin lotion [33]. Treatments were applied overnight and reapplied after 7 days, but follow-up was only conducted for 9 days. During the study, children were isolated in a holiday camp to avoid reinfestation from contacts in the community. Assessments on day 9 showed no lice present in the dimeticone group on 70 of 72 children (97.2%) compared with 48 of 71 (67.6%) in the permethrin group. This per-protocol analysis gave a significant advantage to dimeticone ( $P < 0.001$ , RR, 1.44; 95% CI, 1.22–1.70). One participant was lost from each group, which would have given an ITT outcome of 95.9% success for dimeticone and 66.7% for permethrin.

We found one RCT (60 people, eight drop outs) conducted in the USA that compared 50–50 isopropyl myristate–cyclomethicone (IPM-C) with 0.33% pyrethrum shampoo synergized with 4% piperonyl butoxide; both products were applied for 10 min [34]. IPM-C was applied on up to three occasions a week apart, depending on whether lice were present at an assessment. Pyrethrum shampoo was applied on two occasions a week apart. This study was exceptionally difficult to interpret because primary outcome data were given as percentages and presented graphically and there was no consistency of treatment regimen – every time a patient was found with lice they were treated again, but several missed interim visits. However, the authors stated that 52% of patients treated with IPM-C were louse free at day 21 which was significantly more effective compared with pyrethrum – values not given.

A second RCT of IPM-C (141 children and 27 adults), this time conducted in the UK, compared the product with 1% permethrin crème rinse, both products applied twice for 10 min with a week between [35]. By the 14th day after start of treatment, 91 patients out of 111 (82.0%) treated with IPM-C were louse free compared with 11 of 57 (19%) treated using permethrin ( $P < 0.001$ ; RR, 4.25; 95% CI, 2.48–7.28).

We found one report of two double-blind, multicenter, vehicle placebo-controlled RCTs investigating the activity of 5% benzyl alcohol and mineral oil emulsion (BA/MO) [36]. In both studies the treatments were applied twice, a week apart, and final follow-up was 14 days after the second application. In the first study (125 children), 48 of 63 treated using BA/MO were louse free at day 21 compared with three of 63 in the placebo group. In the second RCT, also of 125 children, the BA/MO preparation eliminated lice from 48 of the 64 patients compared with the 16 of 61 in the placebo group. Over all RCTs and open-label studies, 6.8% of patients treated with BA/MO reported application site discomfort.

We also found a report of one RCT comparison (42 adults and children) between a spray – with a named active of 1% sodium chloride (0.1709 M), with a benzyl alcohol excipient, left on for 24 h, – and a 1% permethrin crème rinse applied for 10 min. Each product was applied once, with a follow-up treatment 7 days later only if lice were found. After one drop out from each group the ITT analysis found 16 people of 21 (76.2%) with no lice in the sodium chloride group after 14 days and nine participants of 21 (42.9%) treated with permethrin (85.0 and 45.0% successful respectively per-protocol) [37]. How much of this activity was truly as a result of salt exposure and how much due to benzyl alcohol is not clear as the dose concentration of benzyl alcohol is not specified on the pack.

We have found another report of two RCTs evaluating 1,2-octanediol, a wetting agent [38]. In the first (520 children and adults) three-center study, a preparation of 1,2-octanediol in 20% isopropanol lotion was evaluated using two application times (2–2.5 h or overnight) in comparison with 0.5% malathion aqueous emulsion. In this study, 1,2-octanediol lotion was significantly ( $P < 0.0005$ ) more effective with successful elimination of lice for 124 of 175 (70.9%) of patients receiving the 2–2.5 h treatment (RR, compared with malathion, 1.50; 95% CI, 1.22–1.85), and when 1,2-octanediol was applied overnight the success rate was 153 of 174 (87.9%) (RR, 1.86; 95% CI, 1.54–2.26) compared with 81 of 171 (47.4%) patients with malathion. The second study (121 children and adults), conducted in two centers, compared the 1,2-octanediol–20% isopropanol lotion, 2–2.5 h with a 1,2-octanediol alcohol-free mousse applied for either 2–2.5 h or for 8 h/overnight. The mousse applied for 8 h/overnight cured 31 of the 40 (77.5%) patients, compared with 24 of the 40 (60.0%) treated using the alcoholic lotion (RR, 1.29; 95% CI, 0.95–1.75; number needed to treat, 5.7) but when the mousse was applied for 2–2.5 h, only 17 from 41 (41.5%) patients were cured (RR, 0.69; 95% CI, 0.44–1.08) compared with the lotion. However, irritant application site adverse events were more common using 1,2-octanediol in the alcoholic lotion at both 2–2.5 h (12.0%,  $P = 0.001$ ) and 8 h/overnight (14.9%,  $P < 0.0005$ ), compared with 0.5% malathion (2.3%). Similar reactions were also found when using the lotion for 2–2.5 h in comparison with the alcohol-free mousse ( $P < 0.045$ ).

We also found one cohort study (41 children) investigating the effect of a more viscous dimeticone preparation using 4% high molecular weight dimeticone in a nonvolatile liquid gel base applied for 15 min on two occasions a week apart [39]. This study found that all lice and their eggs were killed following the first application because no nymphs were observed at any of the four follow-up visits.

More recently we found one RCT (90 children and adults) in which the liquid gel formulation of 4% high molecular weight dimeticone was applied only once for 15 min compared with two applications 7 days apart of 1% permethrin crème rinse. The ITT

analysis found successful treatments in 30 people of 43 (69.8%) of the dimeticone group and seven of 47 (14.9%) in the permethrin group after 14 days ( $P < 0.001$ ; odds ratio [OR], 13.19; 95% CI, 4.69–37.07). The per-protocol outcome was similar, with 27 participants out of 35 (77.1%) cured for dimeticone versus seven of 45 (15.6%) for permethrin [40].

We found a report of one RCT (45 children and adults) that compared a spray containing 20% tocopheryl acetate in a cyclomethicone carrier, applied for 20 min, with 1% permethrin crème rinse, both products applied twice with 7 days between. After 14 days, 20% tocopheryl acetate was significantly ( $P = 0.033$ ) more effective than 1% permethrin, worst case analysis showing 13 successful treatments in 23 people (56.5%) compared with five successes from 22 (22.7%) for permethrin. After addressing anomalies of reinfestation within households, the underlying cure rate was 17 people from 23 (73.9%) for tocopheryl acetate compared with five from 22 (22.7%) (OR, 9.63; 95% CI, 2.46–37.68;  $P < 0.001$ ) [41].

**Drawbacks** We found no drawbacks for 4% dimeticone lotion. It was reported as producing fewer irritant reactions (three of 127 patients, 2%) versus phenothrin liquid (11 of 125, 9%) [27], none (0%) versus malathion (two of 30, 6.7%) [31], and none as a gel [39]. The mixed dimeticone preparation produced two irritant reactions in 73 patients (2.7%) compared with none for permethrin [33]. Similarly, IPM-C produced a low number of adverse events. In the US study, none were specifically reported beyond being “mild” [34]; in the UK study, six adverse events (5.4%) occurred compared with none for permethrin [35]. In all cases with this group of materials the product-related events were application site reactions such as dry skin or erythema, or ocular irritation if the fluid ran into the eyes [36,38–41].

**Comments** Dimeticone has been shown to have a physical mode of action in which it coats the insects, blocks the respiratory system, and disrupts their ability to manage water [42]. This mode of action circumvents resistance to conventional neurotoxic insecticides and is unlikely to be affected by resistance.

Since 2006 there have been numerous products released into the European markets based on silicones and other synthetic oils. At the time of writing, most of these have not been supported by peer reviewed reports, although a high proportion claims to be “clinically proven.”

**Implications for clinical practice** In several countries in Europe, physically disrupting insecticides have almost completely replaced conventional insecticides for louse control. Because they are not affected by the resistance mechanisms that render conventional insecticides ineffective and are not absorbed transdermally, physically disrupting insecticides offer the principal alternative method of treatment, especially for people concerned about using insecticides on safety grounds.

Most physically acting preparations require relatively small quantities for a thorough treatment, mean quantities quoted as around 60 mL. However, prescribing recommendations for BA/MO are for considerably greater quantities, up to 48 fluid ounces (1364 mL) for long hair. Such large volumes are not only difficult to manage physically but also highly costly per treatment.

#### **Antimicrobial and other oral treatments**

**Efficacy** We found one RCT (115 children) in which cotrimoxazole (trimethoprim and sulfamethoxazole), either alone (10 mg/kg per

day over 10 days) or in combination with 1% permethrin crème rinse, was compared with 1% permethrin crème rinse alone (one application, with a second after 7 days if lice remained) [43]. After 2 weeks, the number of children who were louse free with cotrimoxazole alone (28/36, 77.8%) did not significantly differ from the number with permethrin alone (28/39, 71.8%), but the combination treatment (37/40, 92.5%) was superior ( $P < 0.03$ ) to permethrin alone.

We also found one double-blind, double-dummy, RCT (812 patients, 15 lost to follow-up and a total of 35 (6.5%) not completing the study, randomized by the 376 households), conducted in the UK, Ireland, France, and Israel, comparing two doses of oral ivermectin at 400 µg/kg with 0.5% malathion alcoholic lotion, each given on days 0 and 7 [44]. Placebo tablets, given to malathion-treated patients, were identical in composition to those of ivermectin minus the active substance. Ivermectin-treated patients were treated using a placebo lotion of 100% isopropanol. In the ITT analysis, 378 of 397 (95.2%) patients receiving ivermectin were lice free on day 15 compared with 352 of the 414 (85.0%) receiving malathion (absolute difference [AD], 10.2%; 95% CI, 4.6–15.7;  $P < 0.001$ ). In the per-protocol population, 339 of 349 (97.1%) of those receiving ivermectin were lice free on day 15, whereas 327 of 364 (89.8%) patients treated with malathion had no lice (AD, 7%; 95% CI, 2.8–11.8;  $P = 0.002$ ). Patients from both groups who still had lice at day 15 (eight ivermectin, 31 malathion) were switched to the other treatment. At the 29th day all except one patient receiving ivermectin had been cured. In this study, seven of 398 patients (1.8%) receiving ivermectin and five of 414 (1.2%) on malathion withdrew as a result of adverse events. Two serious events occurred: one child receiving ivermectin had a seizure, subsequently diagnosed with a right rolandic (centrotemporal) focus, and another child on malathion was hospitalized as a precaution following a severe headache. Overall, there were 30 (7.5%) treatment-related events in the ivermectin group and 45 (10.9%) in the malathion group.

We found a smaller RCT (80 children), conducted in Egypt, comparing a single dose of either oral ivermectin 200 µg/kg or 0.5% malathion lotion, with a repeat treatment if required [45]. After the single dose, 31 of the 40 (77.5%) patients treated with ivermectin were louse free, as were 35 of the 40 (87.5%) treated with malathion. Following the second treatment dose, for those with lice at day 8, the success rates increased to 92.5% for ivermectin and 95% for malathion.

We found various cohort studies and nonrandomized studies of oral and related treatments. One cohort study (114 schoolchildren) in which cotrimoxazole (8 mg/kg daily over 12 days) plus 1% lindane shampoo applied for 10 min was compared with 1% lindane shampoo alone [46]. If lice were found after 2 weeks, a further treatment was given. No significant difference was found between the treatments at either examination. At 2 weeks, the louse-free rate with lindane shampoo was 53 of 69 (76.8%), compared with 39 of 45 (86.7%) for the combination treatment. The cure rate increased following the second treatment to 63 of 69 (91.3%) for lindane shampoo and 44 of 45 (97.8%) with the combined treatment. Other nonrandomized studies have investigated the activity of thiabendazole (20 mg/kg twice daily for 1 day, with repeat treatment after 10 days) [47], levamisole [48], and ivermectin (200 µg/kg) [49], each of which has shown variable results related to dosing.

**Drawbacks** The RCT comparing cotrimoxazole with permethrin reported three cases of scalp irritation with permethrin and nine

incidents of intense but transient pruritus following cotrimoxazole alone. Three children treated with cotrimoxazole developed allergic rash and were withdrawn, and three others experienced nausea and/or vomiting. Similar side effects have accompanied oral treatments using ivermectin and thiabendazole. In all oral treatment studies dosing may be critical because most of the active compounds are either metabolized rapidly or have relatively short half-lives due to rapid excretion [50]. Additionally, there is some evidence that these materials may have relatively short useful lives because in vitro it has been demonstrated that lice exposed to lower than optimal dosing, such as could occur if too little is given or lice arrive on the head after blood levels have started to decline, over-transcribes detoxification genes that are involved in tolerance/resistance [51].

**Comment** Cotrimoxazole is believed to eliminate the symbiotic microorganisms associated with the gut of lice, inhibiting their viability and development. However, its use is inappropriate for this condition, due to the relatively high risk of adverse reactions to the drug. In one RCT, for example, a quarter of children taking cotrimoxazole developed intense pruritus after 3–4 days, even though it disappeared after 1–3 h. Potentially serious, although rare, adverse effects associated with cotrimoxazole include Stevens–Johnson syndrome, erythema multiforme, and blood disorders.

**Implications for clinical practice** It is unlikely for any orally administered drug to be a first choice for treatment despite current problems with resistance, although it appears to be more acceptable in the USA than Europe. The large RCT comparing ivermectin and malathion conducted in Europe only considered use of the product on cases of infestation nonresponsive to other medications. The introduction of alternatives, such as physically disrupting insecticides and herbal products, is likely to make ivermectin, and especially cotrimoxazole, curious therapeutic anachronisms.

### **Mechanical removal of lice or viable eggs by combing**

**Efficacy** We found one systematic review that evaluated louse removal by combing compared with insecticide treatment, but it did not evaluate nit combing to remove eggs. Three studies compared insecticide treatments with “wet combing with conditioner.” One study, a community-based pragmatic RCT (72 people) included in the Cochrane review, compared “bug-busting” (wet combing with conditioner) with two applications of 0.5% malathion alcoholic lotion 7 days apart [52]. Seven days after the second treatment (day 14), fewer people using malathion (nine of 40, 23%) had lice in comparison with those using “bug-busting” (20/32, 63%). A second small RCT, in which a trained hairdresser performed the first combing treatment or applied the insecticide product, compared a single application of permethrin (1% crème rinse) with “bug-busting” [5]. After 14 days, more people treated with permethrin still had lice (eight of 11 (73%) vs eight of 14 (57%)). We found one RCT (30 people) that compared 0.2% *d*-phenothrin lotion (no terpenoids in the vehicle) applied twice at an interval of 7 days, together with some level of combing (not clearly specified) versus “bug-busting” [53]. After 14 days, the cure rate with phenothrin lotion (two of 15, 15%) did not significantly differ from that with “bug-busting” (eight of 15, 53%). A more recent RCT (133 young people) compared “bug-busting” with insecticide treatment, divided between 0.5% aqueous malathion liquid and 1% permethrin crème rinse [54]. Nine of 70 individuals treated with insecticide – five of 30 (17%) with malathion and four of 40 (10%) with

permethrin – had no lice after 6 days, and 32 of 62 (52%) using “bug-busting” had no lice after 14 days. We found one RCT (95 adults and children) comparing combing with a metal nit/louse comb plus 1% permethrin crème rinse with permethrin alone [55]. Treatments were applied by a health-care professional. If lice were found after 7 days, an additional course of treatment (insecticide or insecticide plus combing) was given. There was no significant difference between the cure rates at 2, 8, and 15 days – louse-free patients at day 2: 49/59 (83%) without combing and 24/33 (73%) with combing; at day 8 before retreatment: 27/59 (46%) with no combing and 11/33 (33%) with combing; and at day 15: 47/60 (78%) without combing and 24/33 (73%) with combing.

We found three RCTs that evaluated different aspects of nit combing using “half-head” studies in which combs were randomly assigned so that one was used on one side of the head and another on the other side. The first RCT (30 children) compared nit combs from different manufacturers of insecticide treatments after using 1% permethrin crème rinse [56]. The combs were not significantly different for removing head lice, but one plastic comb with stepped teeth (Toppyc™, Johnson & Johnson, Brazil) (Figure 52.2) was significantly more effective ( $P = 0.0004$ ) at removing louse eggshells than the other two combs. A second RCT (27 children) conducted in Australia compared a metal pin comb (Licemeister™, National Pediculosis Association, USA) with a plastic comb (Lady Jayne, Richardson Sheffield, UK) after application of a viscous head louse treatment product. No difference was detected in comparing the combs for ability to remove lice, but the metal comb was significantly ( $P < 0.005$ ) better at removing hatched, dead, and live louse eggs [57]. The third RCT from Argentina (50 children) compared two plastic and two metal combs for removal of lice and louse eggs/nits without prior pediculicide use. The plastic combs were generally more efficient at removing lice, with the KSL® (KSL Consulting, Denmark) more efficient than NOPUCID® (ELEA S.A., Argentina), although only significantly ( $P < 0.007$ ) for third-stage nymphs. Comparison of the metal combs found the ASSY® (Assy, Argentina) more efficient on all stages than a KSL metal comb and significantly ( $P < 0.009$ ) at removing eggs of all types [58].

**Drawbacks** We found no evidence of drawbacks from combing alone, apart from discomfort for both the carer and the person

**Figure 52.2** A plastic comb with “stepped teeth,” which have been found to be more effective for removing nits and eggs.

being combed. Potential drawbacks exist for wet combing with conditioner. This requires conditioning crème rinses to be left on the scalp for prolonged periods, but adverse reactions to hair-conditioning agents have occurred after normal limited cosmetic use. Reactions include allergic contact dermatitis, urticaria, urticaria with systemic symptoms, and angioedema [59–63].

**Comment** All four studies comparing insecticide treatments with “bug-busting” were performed in areas in which resistance to the insecticide employed was either recognized before commencing the study or else identified as part of the study. As a result, the potential effectiveness of the insecticides was limited. We found a cohort trial that indicated that a conditioner-like formulation could be an effective pediculicide if allowed to dry on the hair [64]. A similar effect could occur with prolonged combing during “bug-busting.” Studies evaluating nit combing as an adjunct to insecticide treatment used combs that differed considerably in material and construction, so it was difficult to attribute efficacy, or lack of it, to either the pediculicide or the comb.

**Implications for clinical practice** Although combing may seem an attractive, simple, and safe treatment method, there is no real evidence that it is effective, especially when practiced by carers who may have little skill in the method. What little evidence is available indicates that insecticide-based products are more likely to be effective if applied twice with an interval of 1 week, even in areas in which insecticide resistance has developed. No doubt the success of currently used insecticides will diminish further with time, but combing requires better evidence of success before it will replace chemical treatments for the majority of patients.

#### **Herbal treatments and essential oils**

**Efficacy** We found one RCT conducted in Israel (143 children) that compared a spray based on coconut and anise (concentrations not given, product now withdrawn in most countries) with an insecticide spray containing a mixture of insecticides (0.5% permethrin, 0.25% malathion, synergized by 2% piperonyl butoxide, now withdrawn from most countries) [65]. Coconut and anise spray was applied three times at 5-day intervals and insecticide twice 10 days apart. There was no significant difference between the cure rate with the coconut and anise spray (60/70, 86%) and that with insecticide (59/73, 81%).

A second RCT (100 children and adults, with four withdrawals) conducted in the UK compared the same coconut and anise spray applied for 15 min with 0.43% permethrin alcoholic lotion applied for 45 min, both applied twice with 1 week between applications [66]. The spray was significantly more successful with 41 of 50 patients (82.0%) cured compared with 21 of 50 (42.0%) for permethrin ( $P < 0.0001$ ; AD, 40%; 95% CI, 22.5–57.5%). Per-protocol success rates were 40 of 48 (83.3%) and 21 of 48 (43.8%) respectively. Both products proved to be irritant, with 33 people reporting adverse reactions following alcohol contact with excoriated skin and respiratory irritation due to the oil of anise.

We found two RCTs evaluating the efficacy of tea tree oil (melaleuca oil). The first RCT conducted in Australia (132 school children of whom 123 were fully compliant) compared three products: an oily solution containing 10% tea tree oil and 1% lavender oil (TTO/LO) applied for 10 min on 3 days, each a week apart; an aqueous emulsion containing BA/MO also applied for 10 min on three occasions; and a mousse containing 0.165% pyrethrins and 1.65% piperonyl butoxide applied twice for 10 min [67]. Final

assessments were made 1 day after the final treatment for each product; that is, day 8 for the insecticide mousse and day 15 for the two other products. Louse-free outcomes for the ITT populations were 41 of 43 patients (95.4%) for TTO/LO, 40 of 45 (88.9%) for BA/MO, and 10 of 44 (22.7%) for the pyrethrin mousse. In the per-protocol analysis the respective outcomes were 40 of 41 (97.6%), 37 of 37 (100%), and 10 of 30 (33.3%). Both noninsecticide products were significantly ( $P < 0.001$ ) more effective. The TTO/LO product caused significantly ( $P < 0.001$ ) more adverse events, with 20 (46.5%) participants reporting stinging or drying effects at the application site compared with three (6.7%) for BA/MO and four (9.1%) for pyrethrin mousse.

The second RCT (92 children), also conducted in Australia, employed a novel approach to evaluation of ovicidal activity of products [68]. It compared a single application of each of three products: TTO/LO, an oily product containing 11% eucalyptus oil and 1% lemon tea tree oil (EO/LTTO), and BA/MO. After completion of the single application treatment, at least 10 viable louse eggs were removed from each participant and incubated in the laboratory to evaluate the ovicidal effect. Using generalized estimating equations it was found that the ovicidal effects of the three products were  $3.3 \pm 16\%$  for EO/LTTO,  $44.4 \pm 23\%$  for TTO/LO, and  $68.3 \pm 38\%$  for BA/MO. In this study, EO/LTTO caused stinging adverse events in 20% of the children compared with 12.9% treated with TTO/LO. No outcome data were given for the children who were treated.

Another Australian RCT (152 children, 39 noncompliant) compared EO/LTTO solution with 1% malathion shampoo and pyrethrin plus piperonyl butoxide mousse [69]. Both insecticide products were applied twice and the EO/LTTO solution three times, in each case with 1 week between applications. Only per-protocol outcomes were given, in which louse-free rates were 33 of 40 (82.5%) patients on day 21 for EO/LTTO, 13 from 36 (36.1%) on day 14 for the pyrethrin mousse, and 11 of 35 (29.7%) on day 14 for malathion shampoo. Application site adverse events were given for the ITT group as 18 events with EO/LTTO, three with the mousse, and two with the shampoo.

We found one RCT (91 children, 18 noncompliant) evaluating the effects of a shampoo product based on soya oil [70]. This study, conducted in the UK, compared two 30-min applications 9 days apart of soya oil shampoo with two 30-min applications of 0.5% permethrin alcoholic lotion. The soya oil shampoo was significantly ( $P < 0.01$ ) more effective than the lotion for both ITT and per-protocol populations. For the ITT analysis, 28/45 (62.2%) of the participants in the soya oil were louse free on day 14 versus 16/46 (34.8%) in the permethrin lotion group. The AD in rate of success was 27.4% (95% CI, 7–48%). For the per-protocol analysis the respective outcomes were 74.3% for soya oil versus 36.8% for permethrin, AD 37.5% (95% CI, 15–60%). Irritant adverse events were found in 12 people (26.6%) with the shampoo and 11 (23.9%) with the lotion.

**Drawbacks** No clinically detectable adverse effects have been reported for essential oils or herbal extracts, although a potential for toxic effects has been recognized for several essential oils, including anise [71]. One recent case report was of a grand mal seizure in a 4-year-old child triggered by use of a eucalyptus oil product used for treating head louse infestation [72]. It is likely that several essential oils or their components have similar activity to conventional insecticides, and would therefore be affected by similar resistance mechanisms. The tea tree oil component terpenin-

4-ol is recognized as an acetylcholine esterase inhibitor, similar to the activity of malathion, and is possibly affected by malathion resistance. Consequently, results obtained using one herbal combination are unlikely to translate to other herbal mixes using different active materials at different concentrations, especially where different terpenoids in a mixture could have antagonistic and inhibitory effects [73,74].

**Comment** Some activity against lice and their eggs has been identified in vitro, and in uncontrolled studies, for essential oils, their constituent terpenoids, and for several fixed oils (cold pressed), and other plant extracts [71,75–80]. Several products that have been released worldwide as medical devices or combing aids employ plant derived materials as “active” components. Many claim to be “clinically proven” but are not supported by published data from RCTs or even cohort studies.

Herbal and other alternative therapies have become more popular in this application, despite problems with efficacy or irritant side effects. Although terpenoids are a major constituent of some registered products, most alternative therapies use these chemicals at low concentrations to reduce the risk of side effects. Such low doses inevitably select for resistant strains of lice, and some resistance to terpenoids has already been observed in the UK (I.F. Burgess, unpublished).

## What is the best method for diagnosing louse infection?

### Case scenario 52.2

Head louse infections have been reported on some of the classmates of a 9-year-old girl. A few empty louse eggshells are visible on her hair, and she scratches occasionally. How can this evidence of what may be a past infection be distinguished from an active infestation? Is detection combing or direct observation (Figures 52.3 and 52.4) the most efficient way of finding lice?

### Efficacy

We found no systematic reviews and no RCTs evaluating detection methods. One observational study (224 people) compared traditional scalp inspection with wet combing with conditioner. Wet combing found more cases of louse infection in a school than scalp inspection: 49 of 224 (22%) versus 33 of 224 (15%), respectively. However, visual inspection was claimed to identify a further 13 cases not confirmed either by combing or by follow-up examination 2 weeks later [81]. One RCT of treatments found dry combing with a detection comb to be more effective than visual inspection in identifying positive cases before treatment: all of 25 (100%) versus 12 of 25 (48%) [5]. One observational study (268 children) compared the use of a metal louse detection comb with visual inspection of dry or slightly dampened hair [6]. Detection combing was found to be significantly more effective ( $P < 0.001$ ), identifying 68 of 268 (25.4%) children with lice in comparison with 16 of 268 (5.9%) for visual inspection. A second observational study (461 schoolchildren) used a plastic detection comb on dry hair [8]. Detection combing diagnosed lice on 96 of the 461 children (20.8%) in comparison with 30 (6.5%) in whom they were found by visual inspection [82]. In a third observational study (241 schoolchildren), two metal pin combs with different tooth spacing were each evaluated in a different school. A comb with 0.18 mm spacing found five children from 95 (5.3%) to have lice compared with a comb having a gap of 0.15 mm, which found five children infested out of 146 (3.4%). No infestations were detected by visual screening and

Figure 52.3 Standard detection comb for head lice.

there was no significant difference between the combs for efficiency of detecting lice or louse eggs [83].

#### **Comment**

Accurate diagnosis of an active head louse infestation is fundamental for deciding whether treatment is needed. The presence of apparently viable louse eggs close to the scalp was once considered sufficient evidence of an active infection. Now, only the presence of mobile stages is considered adequate evidence [10]. One cohort study (50 people) confirmed that the presence of eggs close to the scalp is a limited risk factor. Children screened by direct observation of the scalp, and found only to have louse eggs, were evaluated again 14 days later. Those with five eggs or more within 6 mm of the scalp were more likely to develop an active infestation than those with fewer than five eggs (seven of 22 vs two of 28). It was concluded that many children are excluded from school or treated unnecessarily and that repeated examinations to determine whether an infestation develops would be more beneficial [82].

Unnecessary treatments and school exclusions also arise because caregivers and health professionals misdiagnose items found in the hair. An observational study evaluating 614 samples of presumed head lice found that only 364 (59%) were louse related, showing that better diagnostic tools are required [84].

#### **Implications for practice**

Accurate diagnosis is essential for developing an appropriate treatment strategy. Treatment should only be given if living lice are found. Too often, children are exposed to treatments unnecessarily because a parent finds a few empty louse eggshells in the hair. However, if a child has never had head lice before, an infection may run for several weeks before it is discovered by chance, because there is no overt sign of the infestation [7,23]. Prescribers should therefore always ask for evidence of active infestation (e.g., a louse stuck to a piece of paper) before deciding on treatment.

#### **Can hair cutting or shaving be used to control head lice?**

There is a widespread belief that cutting hair short or even shaving of the scalp can either make it difficult for lice to live or may even

Figure 52.4 Detection combing for head lice using a standard plastic detection comb.

eliminate infestation, citing that boys suffer fewer infestations because they have shorter hair. The lower incidence and prevalence in boys is more likely associated with sociological factors and patterns of play rather than hair length [84,85]. Hair length per se is probably not a factor influencing infestation, but hair mass may be more important [86]. Certainly, greater masses of hair are more difficult to examine for presence of lice and may also present problems with respect to treatment application. In addition, grooming and styling practices probably have an influence on the survival of lice and their ability to establish a habitat [87–89].

Cutting hair short certainly makes grooming easier and finding whether lice are present much simpler. However, in itself it has no influence on either the presence or the survival of lice. Frequently, we have encountered boys with hair as short as 10 mm who have been virtually dismissed by parents as “never getting lice” who have actually had more parasites present than their longer haired girl siblings.

In some cultures it is commonplace for boys, and girls below a certain age, to have their heads shaved on a regular basis. This may be for control of parasites, for comfort during hot summer months, or in the belief that it makes the hair grow thicker or darker in color. Shaving was advocated by one writer as an effective and a safer practice than use of insecticides for eliminating lice, having experienced problems with poisoning when institutionalized retarded children licked each other's treated hair [90]. However, this practice was considered not to be acceptable in other cultural regions by a different correspondent on the basis that it is only a short-term solution, is stressful for children, and normally a last desperate measure for frustrated parents [91].

There is little or no evidence that hair shaving has any influence on the risk or persistence of infestation, and in order to ensure that it has any lasting effect shaving must be performed on a regular basis. In our clinical studies conducted in Bangladesh in the early

1980s we regularly encountered children who chose to shave their heads in hot weather. It was invariably the case that they were reinfested within a few days, when hair shafts were no longer than 2–3 mm, and we have also encountered an adult male in the UK who was infested despite having apparently shaved his head only 2–3 days previously (I.F. Burgess, unpublished data). Consequently, it can only be concluded that shaving and cutting of hair are of such limited effect that they should not be considered as part of a head louse control or elimination regimen.

### Key points

- Permethrin and malathion have limited efficacy against head lice, due to resistance. There is limited evidence for other insecticides such as lindane and phenothrin, which have now been withdrawn from most countries. Newer insecticides, such as spinosad and ivermectin, have only been evaluated versus placebo.
- Dimeticone is effective against head lice resistant to conventional insecticides and is a treatment of choice in many countries.
- Isopropyl myristate is also probably effective against head lice resistant to conventional insecticides.
- There is limited evidence for the effectiveness of oral cotrimoxazole, which is supposed to eliminate the symbiotic microorganisms associated with the gut of lice. Potential side effects associated with this material make it of limited applicability to head louse treatment.
- There is good evidence for oral ivermectin, although there are questions about dosing and long-term sustainability of what is probably a third-line treatment.
- There is insufficient evidence of the effectiveness of combing alone or in combination with insecticide treatment for either removing lice or nit combing.
- There is limited evidence for the effects of herbal treatments and essential oils as alternative treatments for head lice.
- Combing with a plastic detection comb appears to be the most effective method for finding live lice, but diagnostic methods have been little studied.
- There is no evidence of effectiveness for hair cutting or shaving.

# Insect bites and stings

**Belen Lardizabal Dofitas**

Department of Dermatology, St. Luke's Medical Center, E. Rodriguez Blvd., Quezon City, Philippines  
University of the Philippines College of Medicine & Philippine General Hospital, Metro Manila, Philippines

## Background

### Definition

Insects comprise the most diverse group of animals on the Earth. The true insects are invertebrate species with six legs and three body segments: head, thorax, and abdomen. Many people would consider spiders, mites, and ticks as insects too, although these are arachnids, having eight legs and two body segments only. A more inclusive term than “insects” would be “arthropods,” comprising insects, arachnids, and other invertebrates with paired jointed legs [1].

Insect bites and stings are common occurrences. Bites often appear as wheals or extremely pruritic papules. Bee stings produce an immediate burning sensation and pain, followed by localized swelling and redness. Severe reactions such as anaphylactic shock can occur due to venomous stings [2]. Although these bites may seem inconsequential, insect-related diseases constitute a tremendous burden on the world's population.

This chapter focuses on common problems due to mosquito bites, Hymenoptera stings (bees, wasps), ticks, sand flies, and sand fleas.

### Incidence/prevalence

Insects are found in almost all parts of the world. Mosquitoes are considered the most common nuisance insects and the most important vectors of arthropod-borne diseases.

Blood-feeding insects carry and transmit various pathogens, leading to insect-borne diseases such as malaria and dengue. The World Health Organization estimates that there are 149–274 million cases of malaria yearly, resulting in 537 000–907 000 deaths in 2010 (WHO Global Malaria Programme 2011) [3]. The World Health Organization currently estimates there may be 50–100 million cases of dengue infection worldwide annually [4]. Systemic allergic reactions to insect stings have been reported to occur in 0.3–4% of individuals [5]. Deaths due to allergic reactions to Hymenoptera stings occur in 0.09–0.45 per million inhabitants [6].

Nuisance arthropod bites and the diseases they transmit have caused more loss to military troop strength than direct combat itself

[7]. About 70% of American army personnel reported experiencing significant problems because of arthropods, especially mosquitoes [8]. Work efficiency is also reduced by the nuisance of painful or pruritic bites, secondary infections, and allergies [7,9].

### Etiology/risk factors

Clinically important insects include mosquitoes, flies, lice, beetles, bedbugs, ants, bees, wasps, butterflies, moths, and fleas, among others [2].

Most venomous insects bite or sting in defense of their hives or nests. Nonvenomous insects bite in order to feed on human or animal blood. Biting insects such as mosquitoes and sandflies are generally considered a nuisance due to skin reactions to the bites. Substances in the insect's saliva cause allergic or irritant reactions. The bites are rarely harmful, but insects can be vectors of diseases, some of which are potentially fatal [2].

When bees sting, they leave the sting and venom sac attached. Venom continues to pump in through the stinger until the sack is empty or the sting is removed. Wasps and hornets, however, do not leave their stings behind and can sting repeatedly [10].

Many factors influence the feeding habits of arthropods, such as season, time of day, or preference for indoor or outdoor feeding [11]. Mosquitoes are attracted to human skin that is moist, warm, and with high levels of natural steroids on the skin surface. Persons who exhale more carbon dioxide (i.e., adults, pregnant women), certain odors, lactic acid, and types of sweat compounds also attract more mosquitoes [12].

### Aims of treatment

The aim of treatment is to reduce the severity and duration of local and systemic reactions to mosquito bites, Hymenoptera insect stings, and sand fleas (*Tunga penetrans*).

### Outcomes

- Risk reductions in the severity and duration of symptoms (itching, pain, swelling, local and systemic reactions such as urticaria, angioedema, hypotension, bronchospasm, anaphylactic shock).
- Adverse effects of treatment.

## Aims of prevention

- To reduce the risk of bites due to mosquitoes, ticks, sand fleas, and sand flies.

## Outcomes

- Number of insect bites or rates of insect catches.
- Protective efficacy or risk reductions of insect bites due to protective measure.

## Search methods

Search and appraisal (May 2012) of Medline (1966 to August 2012), Cochrane Library Issue 1, 2012, and the Cochrane Skin Group Specialized Register.

## Questions

### Case scenario 53.1

A 19-year-old man developed extremely pruritic, red papules on his arms and legs after an outdoor hike (Figure 53.1).

### How effective are treatments to reduce mosquito bite allergic reactions?

We found no systematic reviews.

#### Oral antihistamines versus placebo

We found two randomized, double-blind, placebo-controlled, crossover trials investigating oral antihistamines. Cetirizine 10 mg reduced immediate and delayed cutaneous reactions in 18 mosquito-sensitive patients who were exposed to mosquitoes in the field. After 24 h, the mean wheal size was reduced by 41% and the mean pruritus score was reduced by 67% [13].

A study investigated the efficacy of loratadine in 28 children (aged 2–11 years) who were sensitive to mosquito bites. Prophylactically administered loratadine (0.3 mg/kg) significantly decreased the mosquito bite wheal size by 45% and pruritus by 78% and also reduced the size of the bite lesions after 24 h [14].

Figure 53.1 Acute insect bite reactions on the leg.

### How effective is symptomatic treatment for skin reactions to mosquito bites?

We found no systematic reviews. There were no randomized controlled trials (RCTs) or controlled clinical trials investigating topical corticosteroids.

#### Topical treatments versus placebo

We found four RCTs that investigated topical remedies for mosquito bite lesions. A double-blind, placebo-controlled RCT conducted in 25 healthy individuals studied the effects of ammonium sulfate solution in relieving immediate cutaneous reactions to controlled mosquito bites. The ammonium solution reduced itching, burning, and pain and gave complete or partial relief in 64% of the treated forearms, in comparison with none in the placebo-treated arms [15].

Two RCTs studied homeopathic after-bite gels. A placebo-controlled, intraindividual RCT tested 68 healthy volunteers who were each bitten by laboratory-reared mosquitoes on three spots in the volar forearm. There were no statistical differences in pruritus and erythema between the treated, placebo, and untreated bite lesions [16]. A double-blind, intraindividual RCT tested a homeopathic after-bite gel (Prrrikweg gel) in 100 healthy volunteers and found no difference in erythema and pruritus in comparison with the placebo gel [17].

A double-blind RCT tested a topical antihistamine, dimethindene gel, with regard to relief of pruritus due to insect bites and sunburn. Mosquito bites were most frequently treated. If only the first bite or burn was taken into account, 88% were relieved by dimethindene ( $n = 49$ ) within 30 min of application, in comparison with 64% in the placebo group ( $n = 52$ ) ( $P < 0.01$ ) [18].

#### Drawbacks

Five patients (18.5%) reported mild sedation after 10 days of taking cetirizine, in comparison with two patients who took placebo after 5 days [10]. The children treated with loratadine had no marked side effects and tolerated the drug well [14].

No skin irritation or other side effects were reported after the application of topical ammonium or homeopathic gels. Both placebo and dimethindene gel had minor and transient side effects [15–18].

#### Comments

There are few RCTs on the treatment of a very common condition – mosquito bites and allergic reactions to these bites. The reduction of symptoms caused by insect bites has been evaluated for just two of the many oral antihistamines available and for only three types of topical treatment, which surprisingly did not include any topical corticosteroids. For such a common inflammatory skin disorder, insect bites and their treatment deserve further RCTs. The pruritus-relieving effects of dimethindene gel were not specifically for mosquito bites alone.

#### Implications for clinical practice

For mosquito bite-sensitive adults who anticipate exposure to mosquitoes, oral antihistamines such as 10 mg cetirizine may be taken prophylactically to reduce the allergic skin reactions. Loratadine may be given prophylactically to children with allergies to mosquito bites when exposure to these insects is highly possible.

For acute bites by mosquitoes, ammonium sulfate solution may be applied to alleviate the immediate burning, pain, and pruritus. Dimethindene gel may relieve pruritus due to insect bites. The after-

bite homeopathic gels tested have not shown significant benefit in persons without mosquito bite allergy. Topical corticosteroids have not been tested for efficacy in treating mosquito bites in controlled clinical trials or RCTs, but are commonly recommended for acute inflammatory skin reactions, including insect bites.

### What are effective personal protective measures against mosquito bites for travelers in campsites or wilderness locations?

There were no systematic reviews specifically on this topic, but one RCT was found on campers. Most of the evidence found was entomological studies among volunteers.

#### Electronic mosquito repellents

One Cochrane review found 10 field entomological studies that found no statistical difference between the number of mosquitoes caught on exposed body parts of participants using electronic mosquito repellents (EMRs) or no EMR. No quasi-randomized trials or RCTs were found on the efficacy of EMRs on malaria prevention. Marketing EMRs for mosquito bite or malaria prevention were not found to be justifiable [19].

#### Topical insect repellents

There were no systematic reviews or RCTs focusing on travelers. There was one systematic review of controlled laboratory experimental studies on citronella preparations in the prevention of mosquito bites. One broad narrative review that searched PubMed was found on plant-based repellents covering laboratory and field studies. One large field entomological study using a randomized, crossover design testing both plant-based and synthetic repellents was found. We found one RCT that tested a systemic, plant-based repellent against mosquitoes.

#### *N,N*-Diethyl-*m*-toluamide, icaradine, and para-methane-3,8-diol

One crossover RCT conducted in Senegal compared icaradine 20%, para-methane-3,8-diol 20% (PMD, from lemon eucalyptus), 50% *N,N*-diethyl-*m*-toluamide (DEET), and placebo used as spray lotions on the leg of 20 volunteers per day for 5 days. All four active products were statistically significantly superior to placebo and with no significant differences between the four active products

(Table 53.1). The protection afforded by DEET 50% tended to be superior to that of PMD 20% ( $P = 0.07$ ) [20].

#### Plant-based insect repellents

**Citronella repellent** One systematic review found 11 controlled laboratory and experimental published studies that investigated the efficacy of citronella oil or citronella with vanillin. Only one RCT was included. Protection time of citronella oil alone was at least 1.5 h against *Aedes* spp., 3 h against *Anopheles* spp., and 5 h against *Culex* spp. Citronella's protection time was significantly shorter than DEET's [21] (Table 53.2).

#### Systemic mosquito repellent: garlic capsules

One intraindividual, placebo-controlled, crossover RCT ( $n = 51$ ) investigated the mosquito repellence of ingested garlic capsules – two caplets the night before and two caplets at lunch on the day of the study. When volunteers were exposed to laboratory-reared *Aedes aegypti* mosquitoes, no significant mosquito repellence was noted [22] (Table 53.2).

#### Repellent-treated clothing and tents

**Repellent-treated patches** No RCTs were found focusing on travelers, but there was one field trial that tested pretreated patches worn as epaulettes over collars and as bands over cuffs and ankles of male military personnel in India. 12% *N,N*-diethyl-benzamide (Odomos)-, deltamethrin-, or cyfluthrin-impregnated patches, used alone or in combination, were tested on 30 male volunteers in a randomized, crossover trial. Combinations of deltamethrin or cyfluthrin with Odomos had greater repellency than any of the repellents used alone [23] (Table 53.3).

#### Permethrin-treated clothing combined with topical insect repellent use

One small RCT compared the protective effect of DEET 75% solution applied on exposed skin and permethrin-treated clothing, used alone or in combination. Eight male volunteers were exposed to natural populations of mosquitoes for 9-h daytime periods for 8 days. Unprotected test subjects were also exposed to mosquitoes to determine the overall biting rate. DEET combined with permethrin-treated clothing provided the best biting reduction (94.4%) in comparison with treated clothing alone (89.1%), although the difference

**Table 53.1** Topical insect repellents for mosquitoes.

Reference	Population	Species tested	Intervention	Comparison	Outcome	Results	Reporting quality/Comments
Uzzan <i>et al.</i> [20]	Senegal, western Africa $N = 100$ men and women (20 volunteers $\times$ 5 nights)	Various ( <i>Anopheles</i> , <i>Culex</i> , <i>Mansonia</i> , <i>Aedes</i> )	One application of repellent lotion sprays on one leg Crossover RCT • Icaradine 20% • PMD 20% (lemon eucalyptus) • DEET 50%	Placebo	Number of biting mosquitoes captured	Pooled data: 1868 mosquito captures • All four active products were statistically significantly superior to placebo • No significant differences between four active products • Protection afforded by DEET 50% tended to be superior to that of PMD 20% ( $P = 0.07$ ) • Similar protection among various species of mosquitoes • Protective effect of repellents were comparable at 8 p.m. and at midnight	Level 1 evidence Icaradine, PMD, and DEET repellent lotions were efficacious against various species of mosquitoes compared with placebo

Bhatnagar and Mheta [23]	Male military personnel in a garrison, northeast India <i>N</i> = 30 per group × 5 groups (crossed over to each treatment group)	Not specified	Pretreated patches: epaulettes over collars, bands, over cuffs and ankles 1 Deltamethrin 2 Cyfluthrin 3 Deltamethrin+Odomos 4 Cyfluthrin+Odomos	12% <i>N,N</i> -diethyl-benzamide (Odomos)-impregnated patches	Per man-hour biting rate Per man-hour mosquito catches	Deltamethrin or cyfluthrin alone had comparable repellencies compared with Odomos alone Deltamethrin and cyfluthrin had comparable repellencies	Level 1 evidence Large sample size for an entomological study Combinations of deltamethrin or cyfluthrin with Odomos had greater repellency than any of the repellents used alone
Schreck <i>et al.</i> [24]	Eight test subjects	<i>Aedes taeniorhynchus</i> (Wiedemann)	DEET on skin With or without permethrin on clothing 9 h daytime × 8 days/treatment	No DEET on skin With or without permethrin treated clothing 9 h daytime × 8 days/treatment	Number of bites Per 9-h days	DEET + permethrin-treated clothing = 1.5 bites Permethrin-treated clothing only = 53.5 bites DEET only = 98.5 bites Untreated clothing only = 2287 bites (extrapolated) Permethrin-treated clothing reduced biting rates within immediate area by 90%	Level 2 evidence (small sample size) Permethrin-treated clothing combined with DEET on exposed skin afforded a very high protective efficacy against mosquito bites
Boulivaire and Beisang [25]	North America Boy Scout Camp <i>N</i> = 545 (80% boys, 20% adults) From 8 camp sites Treatment group = 761 person-nights Control group = 853 person-nights	Not stated	0.4% permethrin (2.5% permethrin diluted by 7 parts water) sprayed onto external surface of canvass tents Topical insect repellent permitted	No permethrin sprayed onto tents Topical insect repellents permitted	No. of mosquito bites and landings per 5 min	Total 1614 person-nights Average bites per 5 min = 5.1 ± 7.2 (SD) permethrin-treated tents as control RRR mosquito bites and landings = 44% (95% CI: 34–55%) <i>p</i> < 0.001 Insect repellents as control RRR = 36% (95% CI: 25–47%) <i>p</i> < 0.001 – used only during 32% of nights Permethrin vs insect repellent RRR = 20% (95% CI: 4–37%) <i>p</i> = 0.01	Level 1 evidence Pragmatic study design Permethrin-treated tents provided effective passive prophylaxis against mosquito bites

was not significant. There was also no significant difference in bite reduction between DEET (68.7%) and unprotected controls (65.9%), due to bites through untreated clothing [24] (Table 53.3).

**Permethrin-treated tents** One double-blind RCT was conducted among North American campers ( $n = 545$ ), with campsites being randomly allocated to have permethrin-treated tents or untreated tents. The external surface of canvas tents were sprayed once with 0.4% permethrin. The campers were reminded, by means of hand-outs and posted signs, to apply DEET insect repellent within 2 h of dusk. Through daily surveys, mosquito landings and bites (for 5 min at dusk) as well as insect repellent use were self-reported by campers. Permethrin treatment of tents significantly reduced the number of mosquito bites at dusk among campers by 44% (relative risk reduction [RRR]; 95% confidence interval [CI], 33.8–54.7%;  $P < 0.001$ ). Insect repellent use reduced mosquito landings and bites by 36% (95% CI, 25–47%;  $P < 0.001$ ), but no additional benefit was observed among campsites that had permethrin-treated tents. Insect repellent usage only occurred consistently in 15% of subjects [25] (Table 53.3).

### Drawbacks

**Electronic mosquito repellents** Despite the insufficient evidence regarding their efficacy, electronic mosquito repellents are widely marketed and may give a false sense of protection to consumers.

**Topical insect repellents** DEET can dissolve plastic and vinyl and damage rayon, spandex, pigmented leather, and acetate. DEET has reportedly caused dermatitis, allergic reactions, and cardiovascular and neurologic toxicities [12].

Two large case series from poison control centers indicate that the risk of DEET is low. In a 5-year retrospective study conducted in the 1980s, there were five major adverse reactions reported after 9086 exposures to DEET (0.05%). These included hypotension, hypotonic reaction, and syncope, and one death (a suicide ingestion) [26].

In the second report, major adverse reactions to DEET use occurred in 0.1%. These included hypotension, seizures, respiratory distress, and two deaths (0.01%). Among infants and children only, there were 10 major events among 17 252 reported exposures (0.06%), and no deaths. Infants and children accounted for 83.1% of all reported exposures, but the majority of the serious outcomes occurred in adults [27].

**Plant-based insect repellents** Plant-based repellents may contain hazardous ingredients [28], and ingestion of essential oils such as citronella can lead to poisoning [29]. No adverse events were reported after garlic ingestion.

**Repellent-treated clothing or fabric** There were no reported adverse events associated with cloth patches treated with synthetic pyrethroids such as 12% *N,N*-diethyl-benzamide (Odomos), deltamethrin, or cyfluthrin. Although relatively safe and long-lasting when applied to clothing or fabric, permethrin is not recommended as a topical repellent because of safety concerns (e.g., neurotoxicity) upon chronic exposure [30,31].

### Comments

***N,N*-Diethyl-*m*-toluamide insect repellent** The RCTs found had small sample sizes and did not have allocation concealment or blinding. RCTs with adequate sample sizes and improved method-

ology will be able to provide better estimates of the effectiveness and safety of DEET in comparison with no protection or other measures.

**Plant-based insect repellents and alternatives to *N,N*-diethyl-*m*-toluamide** The systematic review on oil of citronella was mainly based on nonrandomized, controlled clinical trials and has a risk of bias. The RCT that investigated garlic may not have detected any effect because only a small dose was ingested. Further clinical trials with increased doses of garlic may be pursued.

There are few RCTs on insect repellents against mosquitoes, but many controlled clinical trials that use DEET as the “gold standard” for testing other chemical and botanical preparations (e.g., IR3535, picaridin, oil of eucalyptus, soy oil, and citronella). RCTs are needed to further validate the effectiveness and safety of these repellents, because some of these are already commercially available, while others may be developed for commercial use and may benefit the countries that possess these indigenous herbs.

**Repellent-treated clothing and tents** The 5-min counts of mosquito bites and landings were reported by campers themselves, creating variability in the outcome measurement. The large sample size and the “real-world” setting of the trial may have offset this limitation of self-reporting. This RCT did not primarily study the effects of insect repellents or DEET in particular, therefore creating bias in the reported estimate of its efficacy.

### Implications for clinical practice

Travelers to mosquito-endemic areas can achieve high levels of sustained protection against bites by using permethrin-treated clothing as well as treated tents. In addition, insect repellents such as DEET may be applied on exposed skin.

Permethrin, like its derivatives, has the advantage of being an insect repellent and an insecticide as well. It is poorly absorbed through the skin and remains active in fabrics even after laundering. It is also quite effective against ticks. DEET has been used worldwide for over 40 years and is found in many commercial insect repellents. It has the added advantage of repelling black flies, chiggers, fleas, and midges as well [12].

The RCTs identified provide evidence regarding efficacy, but do not delve into the practical use of protective measures. The following are suggestions for use based on non-RCT studies and guidelines.

- Avoidance of the insects' habitats, barrier protection (e.g., clothing, bednets), and insect repellents are general measures to prevent insect bites [32]. The combination of “avoid, cover up, and repel” is recommended.
- Mosquitoes can be avoided by staying indoors in insect-proofed dwellings when mosquitoes actively bite – often from dusk to dawn. When outdoors, clothes covering most body parts would be ideal, and the addition of permethrin or other repellents on the fabric would provide a high degree of protection.
- Users must also be reminded that insect repellents do not repel all insects at all times. The repellents must be applied to all exposed areas of skin, because unprotected skin a few centimeters away from a treated area can be attacked by hungry mosquitoes [33].
- The following factors may affect the effectiveness of the repellent: the frequency and uniformity of application, the number and species of the insects, the user's inherent attractiveness to

blood-sucking arthropods, and the overall activity level of the exposed individual [34]. Topical repellents' effectiveness may be reduced when rubbed off or removed by contact with clothing, evaporation and absorption from the skin surface, wash-off from sweat or rain, higher temperatures, or a windy environment [33,35].

- On the basis of a controlled clinical trial, increasing the concentration of DEET does not improve protection but does provide a longer duration of protection. Concentrations of 6.65% protect for about 2h, while 23.8% DEET can last about 5h [36]. The concentrations available for DEET range from 5% to 100%, although the latter is rarely used or indicated. Reapplications are necessary, especially in hot, humid weather, because DEET loses 50% of its effectiveness with every 10° rise in temperature [36].
- Practice guidelines often recommend only one application of low-dose DEET in children, even though the repellent may provide protection for only a few hours. Since there is a lack of evidence on the toxicity of low-dose DEET, reapplication may be done if the child is outdoors for about 4h or more, and especially after swimming or bathing [37].
- The likelihood of side effects would be minimized if the lowest effective concentration of DEET were used for a given situation. Insect repellents and insecticides may have toxic effects, but with proper adherence to the Environmental Protection Agency guidelines and advisories by disease control agencies, these protective measures can be a safe means of preventing insect bites and vector-borne diseases.

### Are insect repellents safe for use among pregnant women? Safety

One vehicle-controlled RCT was conducted in a refugee camp among pregnant women in their second and third trimester of pregnancy (Table 53.4). For an average of 18 weeks, women applied 1.7g DEET per day with thanaka, a paste derived from *Limonea acidiosima* and used as a carrier of the DEET repellent ( $n = 449$ ). The control group applied thanaka 3.2g/day ( $n = 448$ ).

The median total DEET dose was 214.2g per woman (range 0–345.1g). There were no adverse effects on survival, growth, or development at birth or at 1 year among the patients' infants. DEET was detected in 8% of 50 cord blood samples from babies of randomly selected mothers. DEET was not detected in urine samples, indicating efficient clearing of the chemical from their systems. DEET usage reduced the risk of scabies (risk ratio [RR], 0.70; 95% CI, 0.5–0.97), but not of fungal infections. There were no significant adverse neurologic or gastrointestinal effects on the women [38].

### Drawbacks

Skin warming was more frequent among DEET users than thanaka users (80% vs 57.6%;  $P < 0.001$ ). DEET absorption may be enhanced by breaks in the skin; for example, in the presence of other skin diseases. Liver or kidney impairment may also lead to toxicity.

### Comments

In the same cohort of pregnant women, the RCT also investigated the protective effects of DEET against malaria. The RRR was 28% for falciparum malaria and 9% for vivax malaria. However, these results were not statistically significant [39].

### Implications for clinical practice

Evidence from the single RCT including 897 pregnant women suggests that DEET in 20% solution form is safe for pregnant women in their second and third trimesters and does not result in adverse effects on their infants. There has been no evidence so far that DEET is a health risk to pregnant and lactating women or their infants. Potential toxicity exists in conditions that enhance DEET percutaneous absorption or impair its clearing from the body.

### Case scenario 53.2

A 40-year-old man complained of pain and swelling on his hand after being stung by a bee. He was also experiencing difficulty in breathing.

### What symptomatic treatment is effective for skin lesions due to bee or wasp stings?

No systematic reviews were found on this topic. Two RCTs evaluated symptomatic treatment of local reactions after stings by bees, wasps, or hornets (Hymenoptera).

### Pinching versus scraping off the bee sting left in the skin

We found one RCT with two volunteers who either pinched or scraped off honeybee stings (20 stings in each group). The wheal response was greater for stings removed by pinching than for those removed by scraping (80 mm<sup>2</sup> vs 74 mm<sup>2</sup>), but the difference was not statistically significant [40].

### Topical aspirin paste versus ice pack

One RCT studied patients who had just been stung by bees or wasps and who had called a poisons information center for advice. The aspirin group (37 patients) were instructed over the telephone to apply an ice pack followed by topical aspirin paste. The patient was

**Table 53.4** Safety of insect repellents during pregnancy.

Ref.	Population	Species tested	Intervention	Comparisons	Outcomes	Results	Study quality/Comments
McGready <i>et al.</i> [38]	Thai–Burmese border camp $N = 897$ Pregnant women on 2nd and 3rd trimester DEET group = 449 Thanaka = 448 $N = 50$ cord blood samples Randomly selected		$N = 449$ 1.7g DEET per day application with or without thanaka – applied daily after evening shower on exposed arms and legs	$N = 448$ Thanaka 3.2g/day = paste derived from <i>Limonea acidiosima</i> used as carrier of the repellent	Adverse effects on fetus at birth and at 1 year Adverse effect on women	214.2g total median dose DEET/pregnancy $\times$ 18 weeks (average) No adverse neurologic, gastrointestinal, or dermatologic effects on women Median total dose = 214.2g DEET (range 0–345.1g) No adverse effects on survival, growth, or development at birth or at 1 year DEET detected in 8% of cord blood samples	Level 1 evidence Large sample size Pragmatic study design Pregnant women applying DEET lotion daily, with or without thanaka, was not harmful for the fetus at birth and at 1 year

instructed to add a few drops of water to a soluble aspirin tablet and spread this paste over the affected skin. The control group (19 patients) was instructed to apply an ice pack alone to the stings. Swelling at 12 h had resolved in 57% of the aspirin group and in 74% of the ice-pack group (absolute risk reduction,  $-14\%$ ; 95% CI,  $-39\%$  to  $-14\%$ ). Pain at 12 h had resolved in 81% of the aspirin group and 95% of the ice-pack group. Redness persisted for a median duration of 6 h in the aspirin group and only 2 h in the ice-pack group. In both the intention-to-treat and per-protocol analyses, topical aspirin paste was not significantly better than ice packs in reducing pain, swelling, and pruritus [41].

#### **Topical corticosteroids**

No RCTs or controlled clinical trials were found.

#### **Drawbacks**

Topical aspirin paste reportedly increased the duration of redness at the sting sites in comparison with ice-pack application.

#### **Comments**

The RCT on methods of removing stingers also determined that the stinger of honeybees should be immediately removed by whatever means possible, because the time during which the stinger remains embedded in the skin determines the degree of envenomization.

The RCT on topical aspirin assessed clinical effects through telephone interviews, not actual physical examination of patients, although care was taken to standardize the quantification of symptoms.

There are very few RCTs on topical or symptomatic treatments for localized reactions to bee or wasp stings, despite the frequency of this condition. Corticosteroids and antihistamines are often mentioned in treatment guidelines, but there are no RCTs focusing on this topic.

#### **Implications for clinical practice**

Honeybee stings should be removed immediately either by pinching, scraping, or other means in order to reduce the degree of envenomization. Ice packs or aspirin paste may reduce local swelling, pain, and pruritus, but aspirin may prolong redness due to its inherent irritant properties.

#### **What symptomatic treatment is effective for systemic reactions to accidental bee or wasp stings?**

We did not find any systematic reviews or RCTs focusing on this topic.

#### **Implications for clinical practice**

Despite the absence of systematic and reliable evidence in the specific context of insect stings, it is important to know that anaphylactic reactions to insect venoms can be treated in the same way as anaphylaxis from any other cause. Sympathomimetics, antihistamines, and corticosteroids are the most effective drugs for dealing with systemic allergic reactions [42]. For severe reactions (e.g., respiratory or cardiovascular symptoms), two RCTs showed that intramuscular epinephrine was superior to subcutaneous injections in terms of the rapid increase in plasma concentration and start of pharmacological effects [43,44].

An emergency kit for self-medication has been recommended for patients with a known history of systemic reactions. One RCT reported that children (15–30 kg) who self-injected premeasured epinephrine (EpiPen 0.30 mg) had more adverse effects than those

using a lower dose preparation (EpiPen Jr 0.15 mg) [45]. One RCT studied the efficacy of subcutaneous versus inhaled epinephrine preparations among healthy individuals and reported that absorption of epinephrine was more rapid with the inhaled epinephrine [46]. Another RCT reported that 19 children with histories of anaphylaxis were unable to inhale sufficient epinephrine, due to the numerous inhalations required and the bad taste [47].

#### **Is venom immunotherapy effective in preventing systemic reactions to Hymenoptera stings?**

We found one Cochrane systematic review that assessed the efficacy and safety of extracted insect venom on the prevention of further allergic reactions to insect stings [48]. Six RCTs and one quasi-randomized trial of venom immunotherapy (VIT) using standardized venom extract were included with a total of 392 participants. This review covered ant, wasp, and bee immunotherapy. Sublingual (one trial) and subcutaneous VIT (six trials) were tested on individuals with either large local sting reactions or systemic reactions.

This review found that VIT was effective for preventing systemic allergic reactions to insect stings (RR, 0.10; 95% CI, 0.03–0.28). VIT was effective for preventing large local reactions to insect stings (five studies; 112 follow-up stings; RR, 0.41; 95% CI, 0.24–0.69) and for improving quality of life (mean difference (MD) in favor of VIT 1.21 points on a seven-point scale; 95% CI, 0.75–1.67).

#### **Drawbacks**

The Cochrane review on VIT found a small but significant risk of systemic adverse reactions to VIT (RR, 8.16; 95% CI, 1.53–43.46; two studies contributed to the effect estimate). The authors analyzed 11 observational studies and reported that 131/921 (14.2%) participants treated with bee venom VIT and 8/289 (2.8%) treated with wasp venom VIT experienced systemic adverse reactions.

A prospective multicenter study reported that 20% of 840 patients developed systemic reactions to VIT. Systemic reactions occurred in 1.9% of injections during the dose-increase phase and 0.5% of injections during the maintenance phase. The majority of the reactions were mild. Risk factors for systemic reactions were bee venom extract, female gender, and rapid dose increase (rush regimen), but not the severity of insect sting reactions [49].

#### **Comments**

Hymenoptera venom hypersensitivity is potentially life threatening, thus making double-blind, placebo-controlled trials appear unethical. This may explain why only a few RCTs were found. The systematic review on VIT presents good evidence of its efficacy and safety, although some risk of bias was present due to the lack of allocation concealment in five of the trials.

#### **Implications for clinical practice**

VIT, whether sublingual or subcutaneous, showed protective benefit in all studies in terms of reducing the risk of immediate and long-term bee or wasp sting reactions and improving quality of life. Benefit was noted especially for those with prior severe systemic reactions to Hymenoptera venom. In nearly all studies, the effect of VIT was evaluated by measuring the recurrence rates of systemic reactions to re-stings in patients with previous systemic events. Patients with a known history of systemic reactions must be aware that they are at risk of potentially life-threatening reactions to re-stings.

### Does pretreatment with antihistamines reduce the risk of adverse effects of venom immunotherapy?

We found no systematic reviews. Four RCTs have compared oral antihistamines with placebo in rapid dose-increase VIT regimens.

In 140 patients, cetirizine significantly reduced local adverse reactions, but not systemic adverse reactions [50]. In 54 patients, fexofenadine 180 mg given on days 1, 8, 22, and 50 significantly reduced local adverse reactions, but not systemic adverse reactions [51].

In one RCT ( $n = 52$ ), terfenadine 120 mg twice daily significantly reduced local adverse reactions, but not respiratory or cardiovascular symptoms [52].

In the second RCT ( $n = 121$ ), pretreatment with 120 mg terfenadine or terfenadine plus ranitidine significantly reduced both systemic adverse reactions and local adverse reactions during the first week of rush immunotherapy. Therapeutic benefit was evident during the first 4 weeks of treatment [53].

### Drawbacks

Side effects of the antihistamine pretreatment were reported in only one of the above RCTs: headache in 2% (two of 82) and nausea in 1% (one of 82) of the patients who received terfenadine, and fatigue in 3% (one of 39) of those who received placebo.

### Comment

The influence of premedication with terfenadine was assessed after an average of 3 years' follow-up. None of the 20 patients who received terfenadine prior to VIT had reacted to subsequent bee-sting challenges, whereas six of 21 (29%) of the placebo pretreatment group had mild to moderate systemic allergic reactions. These findings indicate that the efficacy of VIT was not adversely affected and may have been enhanced by antihistamine premedication [54].

### Implications for clinical practice

The data suggest that pretreatment with antihistamines such as cetirizine, fexofenadine, and terfenadine may reduce cutaneous adverse reactions to rush or ultra-rush VIT. Terfenadine with or without ranitidine may reduce systemic adverse reactions during the first 4 weeks of rush VIT. The efficacy of VIT is not affected by antihistamine premedication.

### Case scenario 53.3

A 30-year-old male hikes through the woods and notices several ticks attached to his clothing and exposed skin, causing an itchy rash.

### What protective measures are effective against tick bites?

Two RCTs investigating topical repellents, one RCT on color of clothing, and two RCTs on education intervention packages were found (Table 53.5).

### Topical repellents

Two RCTs were found on topical repellents for the prevention of tick bites. DEET plus ethylbutylacetylaminopropionate (EBAAP) was applied daily by forestry workers on exposed skin and compared with placebo ( $N = 276$ ). Total repellent effectiveness (TRE) against tick attachment was reported as  $RRR = 41.1\%$  (95% CI, 2.5–79.6%) and TRE on arms was 66% (95% CI, 17.3–114.7%). Combination of DEET and EBAAP topical repellent on exposed skin was considered moderately effective in reducing the risk of tick bites compared with placebo [55].

Lemon eucalyptus extract (citriodiol) spray was applied daily by healthy volunteers for 2 weeks to lower extremities then crossed over to no repellent use for another 2 weeks ( $N = 111$ ). The median number of attached ticks per person decreased from 1.5 (range 0–9) to 0.5 (range 0–2) ( $P < 0.05$ ) during citriodiol use [56].

### Dark versus light clothing

Ten healthy volunteers wore light-colored clothing and were crossed over to dark clothing on different days before they walked through a tick-infested area. A mean difference of 20.8 more ticks per person were found when light-colored clothing was worn [57].

### Educational programs

One RCT evaluated the effectiveness of a theory-based educational program to prevent Lyme disease and other tick-borne illnesses (TBIs). Among 30 164 ferry passengers traveling to an endemic area, there were lower rates of TBI among participants receiving TBI education compared with control participants receiving bicycle safety education (RR, 0.79). A 60% reduction in risk was observed among those receiving TBI education among those who visited the endemic area for more than 2 weeks compared with control participants (RR, 0.41; 95% CI, 0.18–0.95;  $P < 0.038$ ). Precautions (i.e., use repellent, protective clothing, limit time in tick areas) and checking themselves for ticks were also significantly more likely among TBI-educated participants [58].

Another RCT compared the effects of tick-related educational material versus general health-related educational material, both delivered bimonthly through mail to 317 residents of an endemic area for Lyme disease. After the 6-month intervention period, tick-related educational material was associated with an increase in the knowledge, attitude, behavior (KAB) measures in the intervention group, but this change was not associated with change in anti-recombinant tick calreticulin antibody (ARTCA) levels [59].

### Drawbacks

There were no reported adverse effects associated with EBAAP and citriodiol topical repellents or the education packages tested.

### Comments

The RCTs testing topical repellents, clothing, and education interventions used pragmatic study designs and large sample sizes, thus increasing the strength of evidence regarding their effectiveness.

### Implications for clinical practice

Topical repellents containing a combination of DEET and EBAAP (also known as IR3535) or lemon eucalyptus extract (citriodiol or PMD) may provide moderate protection against tick attachment and should be applied on exposed skin by travelers or workers in tick-infested areas. Education packages are effective in the prevention of TBIs and should be implemented in areas that are endemic for Lyme disease and other TBIs.

### Case scenario 53.4

A 9-year-old boy from an urban squatter settlement in Brazil has intense pruritus, inflammation, and pain on his heels and toes due to sand fleas (*Tunga penetrans*).

### What are effective treatments and preventive measures for sand flea infestations?

One RCT on prevention and two RCTs on treatment were found, all conducted in Brazil (Table 53.6).

Table 53.5 Preventive measures for tick bites.

Ref.	Population	Species tested	Intervention	Comparison	Outcome/s	Main Results	Comments
Staub <i>et al.</i> [55]	Switzerland N = 276 Forestry workers and orienteers N = 138 per group	NS	Combination DEET and EBAAP topical repellent on exposed skin ×6 months	Placebo ×6 months	RRR or percentage effectiveness Average no. of ticks per hour spent in wooded areas	(1) Average number of ticks per hour spent in wooded areas: Repellent = 0.17 placebo = 0.10 $p < 0.05$ (2) Total repellent effectiveness (TRE) against tick attachment: RRR = 41.1% (95% CI, 2.5–79.6%) TRE on arms = 66% (95% CI, 17.3–114.7%) No significant difference in average of unattached ticks	Level 1 evidence Combination DEET and EBAAP topical repellent on exposed skin is moderately effective in reducing the risk of tick bites compared with placebo
Gardulf <i>et al.</i> [56]	Sweden N = 111 volunteer healthy, outdoor active adults living in highly infested areas	<i>Ixodes ricinus</i>	Lemon eucalyptus extract (citriodiol) spray daily ×2 weeks to lower extremities then crossover to no repellent use	No repellent on any part of body for 2 weeks then crossover to lemon eucalyptus spray ×2 weeks	Number of observed attached ticks, not yet attached ticks Anatomical location of ticks	Citriodiol group = 42 attached ticks during use No citriodiol = 112 attached Median number attached ticks per person decreased from 1.5 (range 0–9) to 0.5 (range 0–2) $P < 0.05$ during citriodiol use Number of attached ticks below waist: 13/42 (31%) with citriodiol 73/112 (65%) without spray $p < 0.001$	Level 1 evidence Lemon eucalyptus extract spray (citriodiol) on lower extremities is effective in reducing the number of attached ticks compared with no repellent use Limitation: total tick count used
Stjernberg and Berglund [57]	Sweden 10 volunteers	NS	Light clothing (alternately worn before new exposure)	Dark clothing (alternately worn before new exposure)	No. of bites on clothes No. of nymphs, adult ticks	886 nymph ticks collected overall mean differed significantly 20.8 more ticks per person on light clothing All participants with light clothing had more ticks in all periods of exposure	Level 2 evidence Small sample size Dark clothing may reduce the number of ticks compared with light-colored clothing
Daltroy <i>et al.</i> [58]	Travelers to southeastern Massachusetts, USA N = 30 164 ferry passengers	NS	Theory-based educational program on prevention of Lyme disease and tick-borne illnesses (TBIs)	Bicycle safety education	Precautionary and tick check behaviors	<ul style="list-style-type: none"> <li>Lower rates of TBI among participants receiving TBI education compared with control participants receiving bicycle safety education (relative risk, RR = 0.79)</li> <li>60% reduction in risk among those receiving TBI education who visited the endemic area for more than 2 weeks compared with control participants (RR = 0.41, 95% CI, 0.18–0.95, <math>p &lt; 0.038</math>)</li> <li>Precautions (i.e., use repellent, protective clothing, limit time in tick areas) and checking themselves for ticks were also significantly more likely among TBI-educated participants</li> </ul>	Level 1 evidence Theory-based Lyme disease prevention program can increase precautionary behavior and result in a significant reduction in TBI
Malouin <i>et al.</i> [59]	Baltimore, MD, USA N = 317 Endemic area for Lyme disease	NS	Tick-related educational material Bimonthly through mail ×6 months	General health-related educational material Bimonthly through mail ×6 months	(1) Knowledge, attitude, behavior (KAB) response through questionnaire (2) Anti-recombinant tick calritectulin antibody (ARTCA)	(1) Tick-related education material – increased percentage desired response on KAB measure related to examining body for tick and insect repellent use (2) Only 6/37 models had significant relation between change in KAB and change in ARTCA levels	Level 1 evidence Tick-related educational material was associated with an increase in the KAB measures in the intervention group, but this change was not associated with change in ARTCA levels

### Topical plant-based repellent lotion: coconut oil, jojoba oil, Aloe vera lotion (Zanzarin)

The sand flea infestation of 131 children and adults was first treated with coconut oil, jojoba oil, *Aloe vera* lotion (Zanzarin) for 4 weeks before they were randomly assigned to one of three cohorts: twice-daily application for 1 week every second week or every fourth week or no application of any repellent over a 5-month period after initial

treatment. The intensity of infestation, viable lesions, proportion of manipulated lesions, and clinical pathology were all reduced significantly, especially when Zanzarin was applied every 2 weeks [60].

### Ivermectin, metrifonate, thiabendazole lotions and ointment

In an earlier study, ivermectin, thiabendazole, metrifonate lotions, and thiabendazole ointment were tested on 108 children and adults

Table 53.6 Prevention and treatment of sand fleas infestation.

Ref.	Population	Species tested	Intervention	Comparison	Outcomes	Main results	Study quality/Comments
Buckendahl et al. [60]	Brazil N = 131 Cohort 1: 46 Cohort 2: 34 Control: 51	<i>Tunga penetrans</i>	Coconut oil, jojoba oil, <i>Aloe vera</i> lotion (Zanzarin) Phase 1: twice daily application on feet $\times$ 4 weeks Phase 2: 5 months Cohort A: apply twice daily every 2nd week Cohort B: apply twice daily every 4th week	Cohort C: no application	<ul style="list-style-type: none"> <li>Intensity of infestation</li> <li>Viable lesions</li> <li>Percentage manipulated lesions</li> <li>Clinical pathology</li> </ul>	Cohort 1 (intermittent application of Zanzarin for 1 week every 2nd week) significantly reduced infestation intensity from a median 4 lesions (IQR 1–9) during the whole transmission season Cohort B (application of the repellent every 4th week): infestation intensity remained twice as high (median 8 lesions, IQR 9–16; $p = 0.0035$ ) Control cohort C: infestation intensity 3.5 times as high (median 14 lesions; IQR 7–26; $p = 0.004$ ) Tungiasis-related acute pathology very low in cohort A (median severity score 2; IQR 1–4) compared with cohort B (median severity score 5; IQR 3–7; $p = 0.001$ ), and control cohort C (median severity score 6.5; IQR 4–8; $p = 0.001$ )	Level 1 evidence Moderate risk of bias – blinding of patients, clinicians, and outcome assessors not possible due to distinctive odor of lotion Reinfestation and tungiasis-associated morbidities can be minimized through intermittent application of a plant-based repellent lotion (coconut oil, jojoba oil, <i>Aloe vera</i> )
Heukelbach et al. [61]	Brazil Children >1 year old and adults N = 108 No. of feet infested: 169	<i>Tunga penetrans</i>	Ivermectin lotion Thiabendazole lotion Thiabendazole ointment Metrifonate lotion	Placebo lotion	No. of lesions on feet	Ivermectin lotion, metrifonate, thiabendazole ointment and lotion can each significantly reduce the number of lesions	Level 1 evidence
Heukelbach et al. [62]	Brazil Children >5 years old and adults Total N = 54 Ivermectin: 27 Placebo: 27 Total no. lesions: 192	<i>Tunga penetrans</i>	Ivermectin (oral) 300 $\mu$ g/kg body weight Single dose Repeated after 24 h	Placebo	<ul style="list-style-type: none"> <li>Clinical stage of lesion</li> <li>Presence of erythema pain, itching, signs of viability of fleas</li> <li>Total lysis of fleas</li> </ul>	<ul style="list-style-type: none"> <li>Ratio of total lysis per total number of fleas was slightly higher in ivermectin group</li> <li>No significant difference on any other outcome measures</li> </ul>	Level I evidence Low risk of bias Oral ivermectin 300 $\mu$ g/kg body weight given at 2 doses 24 h apart was not proven to be efficacious for treatment of embedded sand fleas

and found to significantly reduce the number of lesions on their feet compared with placebo lotion [61].

### Oral ivermectin

Oral ivermectin was given at 300  $\mu$ g/kg body weight single dose and repeated after 24 h to 54 patients who were over 5 years of age. The ratio of total lysis per total number of fleas was slightly higher in the ivermectin group and no significant difference on any other outcome measures was observed when compared with placebo [62].

### Drawbacks

There were no adverse events reported among patients who used the topical repellents. For oral ivermectin, adverse events were reported in six cases. Three patients complained of headache, two of abdominal pain, and one of sore throat. In the placebo group, three patients complained of headache and three of pruritus.

### Comments

The study on Zanzarin repellent had a moderate risk of bias because blinding of patients, clinicians, and outcome assessors was not possible due to the distinctive odor of the lotion. Nevertheless, this RCT showed good evidence of its preventive efficacy against tungiasis.

### Implications for practice

The observed superiority of the intermittent application of Zanzarin repellent in preventing reinfestation by sand fleas makes it a feasible intervention. This repellent appears to be affordable and can probably be produced using local coconuts and *Aloe vera* even in resource-poor settings. Oral ivermectin cannot be recommended at this point owing to lack of good evidence on its efficacy against embedded sand fleas.

### Clinical scenario 53.5

A 45-year-old female is planning to travel to a country that is endemic for sand flies that transmit leishmania.

### What are effective topical preparations to reduce sand fly bites?

One RCT investigated the efficacy and safety of a soap composed of 20% DEET plus 0.5% permethrin repellent soap (Nopikex) in the prevention of sand fly bites (Table 53.7). Among the 18 volunteers, the coefficient of protection of this soap was 100% immediately after use versus 67% with placebo soap or no treatment. The knock-down action of the soap on sand flies, however, was not significant [63].

Table 53.7 Prevention of sand fly bites.

Ref.	Population	Species tested	Intervention	Comparisons	Outcomes	Main results	Study quality/Comments
Alexander et al. [63]	Valle de Cauca, Columbia N = 18 volunteers (9 assays)	<i>Lutzomyia youngi</i>	20% DEET + 0.5% permethrin repellent soap (Nopikex) Field study	Placebo soap No treatment	<ul style="list-style-type: none"> <li>• Coefficient of protection (CP)</li> <li>• Mortality of sand flies</li> </ul>	DEET + permethrin soap: CP immediately after use = 100% CP after 4 h = median of 44.3% Placebo soap vs no treatment: CP immediately after use = 67.7% (median) Mortality of flies within 24 h exposure – not significant Flies that fed on volunteers – not significant	Level 2 evidence DEET and permethrin soap had significant protection against sand fly bites immediately after use, lasting for 4 h, waning after 8 h, and no protection afforded after 12 h

### Drawbacks

Volunteers complained about the sticky, dry, or tight sensation of the skin after application. There were no reports of itching, tingling, or burning.

### Comments

Since this study had a small sample size, the evidence is inconclusive but shows a trend to benefit in favor of the DEET–permethrin soap.

### Implications for practice

The DEET–permethrin soap is affordable and does not react with plastic, unlike DEET-containing lotions. It is easy to apply but can be quickly rinsed off or removed when sweat is wiped off the skin. The consumer should reapply the soap on exposed skin, especially during the biting hours of the sand flies (i.e., within 2 h before sunset).

## Key points

### Mosquito bites

- We found fair evidence that 10 mg cetirizine may be taken prophylactically by adults to reduce the allergic skin reactions. Loratadine may be given prophylactically to children with allergies to mosquito bites when exposure to these insects is highly possible.
- We found fair evidence that topical ammonium sulfate solution may alleviate immediate burning, pain, and pruritus.
- We found fair evidence that dimethindene gel may relieve pruritus due to insect bites.
- We found good evidence that after-bite homeopathic gels tested have no significant benefit in persons with mosquito-bite allergy.
- We found no controlled clinical trials or RCTs that topical corticosteroids are effective in treating mosquito bites, although corticosteroids are commonly recommended for acute inflammatory skin reactions, including insect bites.
- We found good evidence that travelers to mosquito-endemic areas may achieve high levels of sustained protection against bites by using synthetic pyrethroid-treated patches and permethrin-treated clothing and tents.
- We found fairly reliable evidence that applying DEET only on exposed skin cannot effectively prevent mosquito bites, because bites can penetrate through untreated clothing. The mosquito-repellent efficacy and safety of alternatives to DEET have not been adequately assessed through RCTs.
- The combination of avoidance of the insects' habitats, barrier protection (e.g., clothing, bednets), and insect repellents are general measures for preventing insect bites.
- We found good evidence that DEET in a 20% solution form is reported to be safe for pregnant women in their second and third trimesters and does not result in adverse effects on their infants.

### Bee and wasp (Hymenoptera) stings

- We found fair evidence that honeybee stings should be removed immediately either by pinching, scraping, or other means in order to reduce the degree of envenomization.
- We found good evidence that ice packs or aspirin paste may reduce local swelling, pain, and pruritus, but that aspirin may prolong redness.
- We found no reliable evidence on emergency treatment specifically for systemic reactions to Hymenoptera stings. However, anaphylactic

reactions to insect venoms can be treated in the same way as anaphylaxis from any other cause. Sympathomimetics, antihistamines, and corticosteroids are the most effective drugs for dealing with systemic allergic reactions.

### Venom immunotherapy in preventing allergic reactions to insect stings

- We found good evidence that VIT is effective for preventing systemic allergic reactions to insect stings, for preventing large local reactions to insect stings, and for improving quality of life.

### Pretreatment with antihistamines in reducing the risk of adverse effects of venom immunotherapy

- We found good evidence that pretreatment with antihistamines such as cetirizine, fexofenadine, and terfenadine may reduce cutaneous adverse reactions to rush or ultra-rush VIT.
- Terfenadine with or without ranitidine may reduce systemic adverse reactions during the first 4 weeks of rush VIT.
- The efficacy of VIT is not affected by antihistamine premedication.

### Tick bites

- We found good evidence that topical repellents containing a combination of DEET and EBAAP (also known as IR3535) or lemon eucalyptus extract (citriodiol or PMD) may provide moderate protection against tick attachment.
- We found good evidence that education interventions are effective in the prevention of TBIs in areas that are endemic for Lyme disease and other TBIs.

### Sand flea bites (tungaiasis)

- We found good evidence that coconut oil, jojoba oil, and *Aloe vera* lotion (Zanzarin) is effective in treating tungaiasis of the feet and that the intermittent application of this lotion effectively prevents reinfestation of the feet by sand fleas.
- We found insufficient evidence that oral ivermectin is effective in clearing sand fleas embedded in feet.

### Sand flies

- We found fair evidence that 20% DEET plus 0.5% permethrin repellent soap provides good protection against sand fly bites immediately after use and up to 4–8 h.

## Acknowledgment

## SECTION 4: Disorders of pigmentation

Hywel C. Williams, editor

### CHAPTER 54

## Vitiligo

Juan Jorge Manriquez and Sergio M. Niklitschek

Department of Dermatology, Pontificia Universidad Catolica de Chile, Santiago, Chile

### Background

#### Definition

Vitiligo is an acquired disorder of pigmentation mainly affecting the skin, in which the loss of functioning melanocytes results in white patches.

#### Incidence/prevalence

Vitiligo is a common skin disorder, affecting about 0.5% of the general population, irrespective of ethnic origin [1].

#### Etiology

There appears to be a genetic predisposition to vitiligo, consistent with a polygenic disorder. However, the pathogenesis of vitiligo still remains unknown. The main hypothesis theorizes an autoimmune process against melanocytes. Other theories include an intrinsic abnormality of melanocytes [2], toxic effect of free radicals [3], an increased release of catecholamines locally [4], and cytomegalovirus infection [5].

#### Prognosis

Although neither lethal nor symptomatic, the effects of vitiligo can be cosmetically and psychologically devastating. The course of the disease is fairly unpredictable, but often progressive [6].

#### Diagnosis

The diagnosis is clinical and based upon the presence of skin patches devoid of pigment.

#### Aim of treatment

The aim of treatment is to achieve partial or total repigmentation, at least for body areas that the patients estimate as “most significant,” with minimal adverse effects.

#### Relevant outcomes

- Physician-rated clinical response: success rate in terms of repigmentation (>75%) and long-term repigmentation rate.
- Side effects of treatment.

#### Methods of search

We searched for randomized controlled trials (RCTs) of currently available medical and surgical treatments at the Cochrane Central Register of Controlled Trials, Medline, and Embase, using the keyword “vitiligo.” The search was completed in June 2012. Where no RCTs were found, information from nonrandomized studies or case series was used.

A Cochrane systematic review (search date November 2009) and a *British Medical Journal* Clinical Evidence systematic review (search date March 2010) were used as a source of RCTs [7,8].

### Questions

#### What are the effects of medical treatment in vitiligo?

##### Case scenario

A 26-year-old woman reports a 10-year history of depigmented areas. Clinical examination reveals symmetrically distributed depigmented areas affecting the sun-exposed areas, mainly upper arms, face and neck (Figure 54.1).

##### Topical therapies

**Topical corticosteroids** One RCT [9] compared topical clobetasol propionate with psoralen plus sunlight therapy (PUVAsoL). Participants receiving clobetasol propionate were significantly more likely than those receiving PUVAsoL to achieve greater than 75% repigmentation (risk ratio [RR], 4.70; 95% confidence interval [CI],

Figure 54.1 Achromic areas on feet of a 35-year-old woman with vitiligo.

1.14–19.39). Another study [10] compared topical clobetasol propionate plus narrowband UVB phototherapy (NB-UVB) versus placebo plus NB-UVB. There was no statistically significant difference between the two groups. One RCT [11] compared topical hydrocortisone plus 308 nm monochromatic excimer light (MEL) versus MEL alone. Participants receiving the combination treatment were more prone to achieve 75% repigmentation than those receiving laser treatment alone (RR, 2.57; 95% CI, 1.20–5.50).

One RCT [12] compared topical betamethasone dipropionate with either calcipotriol or betamethasone dipropionate plus calcipotriol. None of the participants achieved greater than 75% repigmentation.

One RCT [13] found topical clobetasol to be more effective than topical pimecrolimus in the mean percentage of repigmentation (57.7% vs 32.1%, respectively;  $P < 0.05$ ) after 8 weeks of treatment.

One RCT [14] showed no statistically significant difference between topical clobetasol propionate and 0.1% tacrolimus with respect to repigmentation greater than 75%. One RCT [15] compared topical fluticasone propionate (FP) versus FP plus UVA phototherapy or versus UVA alone. No significant difference was seen between participants in the FP plus UVA group and those receiving FP alone in achieving greater than 75% repigmentation. FP alone and with UVA was superior to UVA alone (RR, 3.94; 95% CI, 1.16–13.43).

Topical class 3 corticosteroids have been shown to be effective in localized vitiligo, with a pooled odds ratio (OR) [16] of 14.3 (three RCTs [17–19]; 95% CI, 2.4–83.7); pooled ORs showed nonsignificant differences between topical class 4 or intralesional corticosteroids and their respective placebos [16].

One RCT [20] found that a combination of topical clobetasol and estrogen could be more effective than clobetasol alone in reducing the average area of lesions after 3 months' treatment ( $P < 0.001$ ).

**Drawbacks** All studies examining the effect of topical corticosteroids reported adverse effects, with the more frequent being atrophy, telangiectasia, hypertrichosis, and acneiform papules.

**Intralesional corticosteroids** One study [21] assessed the rate of adverse effects of triamcinolone acetonide injections versus placebo

injections and found atrophy in eight participants, telangiectasia in two, infection in one, and intradermal hemorrhage in one.

**Topical vitamin D analogues: calcipotriol and tacalcitol** Only one RCT [12] examined the effect of calcipotriol as monotherapy (see Topical corticosteroids section).

One RCT [22] compared calcipotriol plus PUVA with placebo plus PUVA. There was no statistically significant difference in the number of participants achieving greater than 75% repigmentation. One RCT [23] compared calcipotriol plus psoralen plus UVA phototherapy (PUVA) with placebo plus PUVA. The side of participants treated with the calcipotriol plus PUVA had a significant fourfold increase in the likelihood of achieving greater than 75% repigmentation sooner than the side treated with placebo plus PUVA (paired OR 4.25; 95% CI, 1.43–12.64). One RCT [24] compared tacalcitol plus MEL with placebo plus MEL. A statistically significantly greater proportion of participants in the tacalcitol plus MEL group achieved greater than 75% repigmentation (RR, 4.50; 95% CI, 1.05–19.35). Another RCT [25] compared tacalcitol plus sunlight versus placebo plus sunlight, but found no difference between the groups.

One study [26] found no significant differences between calcipotriol combined with NB-UVB and NB-UVB alone in achieving repigmentation of lesions.

One RCT [27] compared the effectiveness of NB-UVB alone and combined with tacalcitol. Addition of topical tacalcitol to NB-UVB improved the extent of repigmentation and increased the response rate.

**Drawbacks** The more frequent adverse effects associated with topical vitamin D analogues were mild skin irritation, xerosis (dryness), and itching.

**Calcineurin inhibitors: tacrolimus and pimecrolimus** Only one RCT [14] examined the effect of topical tacrolimus as monotherapy (see Topical corticosteroids section).

A meta-analysis [28] from two studies [28,29] found that topical 0.1% tacrolimus plus MEL was more effective than placebo plus MEL in achieving 75% repigmentation (RR, 3.15; 95% CI, 1.46–6.76).

One RCT [30] compared topical pimecrolimus plus NB-UVB versus placebo plus NB-UVB, finding no statistically significant difference in rates of repigmentation (RR, 3.38; 95% CI, 0.93–12.29).

One RCT [31] found pimecrolimus 1% cream and microdermabrasion to be more effective than pimecrolimus 1% cream alone in achieving more than 50% of pigmentation of the treated patches (60.4% vs 32.1%;  $P < 0.001$ ), over 3 months of follow-up.

**Drawbacks** The more frequent adverse effects associated with topical calcineurin inhibitor were burning sensations, erythema, and localized bullous eruptions.

The United States Food and Drug Administration has warned of a potential malignancy risk from the use of topical tacrolimus and pimecrolimus, principally based on the theoretical risk of immunomodulator utilization. A systematic review and a case-control study were not able to confirm such an association in individuals being treated for atopic eczema [32,33].

**Khellin** One RCT [34] compared the application of khellin in two different vehicles plus UVA versus the vehicles alone plus UVA.

There was no statistically significant difference in repigmentation between any intervention. No significant differences were found in a trial [35] that compared oral khellin and placebo plus sunlight.

**Pseudocatalase and catalase/dismutase superoxide** One study [36] compared Dead Sea climatotherapy plus pseudocatalase cream with Dead Sea climatotherapy plus placebo cream and Dead Sea climatotherapy alone. However, this study did not examine any outcomes of interest. One RCT [37] reported a self-limiting erythematous papular rash in one participant treated with a topical catalase/dismutase superoxide, but did not examine any other outcomes of interest.

**Melagenina (human placental extract)** One study [38] examined the effects of melagenina. However, the study examined no outcomes of interest.

**Comments/implications for practice** It appears reasonable to regard topical corticosteroids as the first-line treatment for localized vitiligo. Topical vitamin D analogues may be an alternative given in combination with light therapies.

Topical tacrolimus seems to be a useful tool, especially for the management of facial skin or eyelid lesions, where the risk of skin atrophy from topical corticosteroids or phototoxicity from phototherapy could be high.

No clear recommendations on the use of khellin, pseudocatalase and catalase/dismutase superoxide, and melagenina can be made on the basis of the current evidence.

### Oral therapies

One RCT [39] examined the effect oral *Ginkgo biloba*, compared with placebo. Overall, *Ginkgo biloba* showed a significant improvement over placebo (RR, 4.40; 95% CI, 1.08–17.95).

One RCT [40] compared the effect of oral minipulses of betamethasone (OMB) with three different combinations of interventions: OMB plus PUVA; OMB plus NB-UVB, and OMB plus broadband UVB phototherapy. There was a statistically significant difference in favor of OMB plus NB-UVB compared with OMB alone (RR, 7.41; 95% CI, 1.03–53.26), but not for OMB plus PUVA versus OMB alone or for OMB plus broadband UVB phototherapy versus OMB alone.

One RCT [41] compared oral azathioprine plus PUVA versus PUVA alone. The combination scheme was statistically significantly more likely to achieve greater than 75% repigmentation (RR, 17.77; 95% CI, 1.08–291.82).

One RCT [42] compared an oral antioxidant pool plus NB-UVB with NB-UVB alone. No statistically significant difference was found between the two groups.

Two RCTs [43,44] found no differences in a quality-of-life index between the use of *Polypodium leucotomos* plus NB-UVB and placebo plus NB-UVB, or between the use of oral levamisole plus topical mometasone furoate and oral placebo plus topical mometasone.

One RCT [45] compared the effectiveness of oral L-phenylalanine, with and without UVA. There was no statistically significant difference between the L-phenylalanine plus UVA group and the no active treatment group, or between the L-phenylalanine alone group versus the no active treatment group.

One RCT [46] compared oral vitamin B12 and folic acid plus NB-UVB with NB-UVB alone. The addition of vitamin B12 and folic acid did not improve any outcome.

**Drawbacks** Nausea was reported with L-phenylalanine, NB-UVB plus *Polypodium leucotomos*, and *Ginkgo biloba*. Weight gain was reported in subjects treated with minipulses of betamethasone.

**Comments/implications for practice** Systemic corticosteroids are not recommended, not only because of the limited evidence of their effectiveness, but also because of the wide range of adverse effects associated with them.

More long-term studies are needed in order to establish the effectiveness and safety profile of oral *Ginkgo biloba* and the possible additive effect of azathioprine when used with light therapies.

No clear recommendations on the use of oral antioxidants or levamisole can be made on the basis of the current evidence.

### Light therapies

**Oral psoralen plus ultraviolet A** There was no statistical difference in repigmentation in participants treated with PUVA compared with NB-UVB [47].

One RCT assessed PUVA in combination with calcipotriol [23] (see Topical vitamin D analogues section). One RCT assessed oral PUVA in combination with azathioprine [41] (see Topical vitamin D analogues section).

**Drawbacks** The more frequent adverse effects associated with PUVA were sedation, xerosis, erythema, exacerbation of acne lesions, and nausea.

**Psoralen plus sunlight therapy** One RCT [48] compared different psoralen compounds, doses, and combinations, combined with exposure to sunlight. One RCT [49] compared oral trimethylpsoralen (TMP) plus sunlight/sun lamp with placebo and the same light exposure in children. One study [50] compared oral PUVAsoL versus topical PUVAsoL versus oral triamcinolone combined with PUVAsoL. One RCT [22] compared topical calcipotriol plus PUVAsoL with placebo combined with PUVAsoL (see Topical vitamin D analogues section). One RCT [40] evaluated OMB plus PUVA, OMB plus NB-UVB, OMB plus BB-UVB, or OMB alone (see Oral therapies section); and one RCT [51] assessed minipunch grafting plus PUVAsoL versus split-skin grafting plus PUVAsoL.

Only two of the numerous comparisons of different psoralen compounds combined with exposure to sunlight were statistically significant and were based on data from one trial [48]: methoxypsoralen plus TMP versus psoralen plus sunlight (RR, 0.35; 95% CI, 0.14–0.87) and methoxypsoralen plus sunlight versus psoralen (RR, 2.50; 95% CI, 1.06–5.91).

**Drawbacks** Adverse effects reported were nausea, pruritus, dizziness, headaches, eye discomfort, and vague gastrointestinal symptoms. There was no evidence of liver or blood toxicity in either group.

**Ultraviolet A** See Topical corticosteroids section.

**Drawbacks** One RCT [15] reported a mild atrophy in areas treated with UVA.

**Ultraviolet B** In one RCT [52] none of the 10 participants receiving either NB-UVB or BB-UVB showed greater than 75% repigmentation after 12 weeks of treatment.

In another RCT, there were no statistical differences in repigmentation in participants treated with MEL from those treated with NB-UVB [53].

In one study, the combined therapy (5-fluorouracil plus Er-YAG laser plus NB-UVB) showed more repigmentation than NB-UVB phototherapy alone (RR, 5.60; 95% CI, 2.31–13.59) [54].

The outcomes for other studies are listed in the Oral therapies section [40,42,46], the Topical corticosteroids section [10], and the Calcineurin inhibitors section [30].

One RCT [55] found no significant differences in repigmentation between NB-UVB light plus a topical formulation including *Cucumis melo* superoxide dismutase and catalase (Vitix), and NB-UVB light alone.

One RCT [56] found no significant differences in repigmentation between pseudocatalase cream and NB-UVB versus placebo and NB-UVB.

One RCT [57] found no significant differences in repigmentation between NB-UVB, topical pimecrolimus, and tacrolimus.

One RCT [58] found no differences in degrees of repigmentation between targeted NB-UVB plus topical tetrahydrocurcuminoid versus targeted NB-UVB alone.

One RCT [59] compared the efficacy of topical PUVA versus NB-UVB. The treatment with NB-UVB was as efficient as with topical PUVA and had fewer adverse effects.

**Drawbacks** Adverse effects associated with UVB phototherapy were itching, hyperpigmentation and mild phototoxic effects.

**Lasers** One RCT [60] evaluated three different regimens of MEL. Repigmentation initiation correlated with treatment number, regardless of frequency. However, repigmentation occurred earlier in the most frequently treated lesions ( $P = 0.0336$ ).

Laser therapies associated with tacrolimus [28,29] (see Calcineurin inhibitors section), topical calcipotriol [61] (see Topical vitamin D analogues section), and topical hydrocortisone [11] (see Topical corticosteroids section) were evaluated.

Three RCTs evaluated percentage of repigmentation >75% [28,29] (see Calcineurin inhibitors section) [11]; (see Topical corticosteroids section).

One RCT [62] found that a combination of MEL and topical 1% pimecrolimus was more effective than only MEL in achieving repigmentation.

**Drawbacks** Laser therapy was associated with burning and/or stinging, moderate to severe erythema, blisters, and edema.

**Comments/implications for clinical practice** On the basis of the current evidence it appears reasonable to regard NB-UVB – alone or plus tacalcitol – as the first-line treatment for moderate to severe generalized vitiligo.

Treatment with MEL, alone or in combination with topical vitamin D analogues, tacrolimus, or topical corticosteroids, seems reasonable according to current evidence, but its utilization may be reduced because of its availability.

### **Surgical interventions**

**Suction blister grafts** One RCT [63] compared suction blister grafts with thin split-thickness grafts. Although repigmentation rates were compared, the study did not assess the primary outcome greater than 75% repigmentation. The only outcome of interest was adverse effects.

In another RCT [64], participants either underwent transplantation of cultured autologous melanocytes plus PUVA therapy (CMP) on one limb and PUVA only (PO) on another, or suction blister transplantation plus PUVA (SBP) on one limb and cryotherapy plus PUVA (CP) on another (see Oral psoralen plus ultraviolet A section).

**Punch grafts, minigrafts, and split skin grafts** One RCT [51] assessed minipunch grafting plus PUVAol versus split-skin grafting plus PUVAol. One study [65] made a five-way comparison between autologous skin minigraft plus 8-methoxypsoralen, minigraft plus placebo, minigraft alone, 8-methoxypsoralen alone, and placebo alone. No outcomes of interest were addressed and no adverse effects were reported. One RCT [66] compared pigmentation spread resulting from the use of a topical corticosteroid (0.1% fluocinolone acetonide) after punch grafting versus PUVA therapy after punch grafting (see Topical corticosteroids section).

One systematic review was found [67], based on case series only (a total of 39 series, reporting on five different techniques). The highest success rates occurred with split-thickness grafting and suction blister epidermal grafting, with 87% of patients achieving >75% repigmentation (sample-size weighted averages; 95% CI, 82–91 and 83–90, respectively). With minigrafting, 68% of the patients (95% CI, 62–64) were successfully grafted. A trial comparing minigrafting and suction blister epidermal grafting [68] confirmed the results of the review, although the outcome measure was the proportion of patches rather than the proportion of patients.

In a placebo-controlled trial including 18 patients, the addition of a melanotropin analogue applied topically on minigrafted patches did not improve the success of the minigrafting [69].

**Drawbacks** Cobblestoning, superficial scarring, and variegated appearance were associated with the minipunch grafting group. In the split-skin grafting group, superficial scarring was observed in all cases, as also were hypertrophic scarring, depigmentation, tire-pattern appearance, milia formation, and rejection of grafts.

**Melanocyte transplantation** One RCT [70] assessed a technique involving transplantation of epidermal cell suspension obtained from a skin graft. No statistically significant difference was found between the groups with respect to the number of participants achieving greater than 75% repigmentation.

**Drawbacks** The only adverse effect reported [70] was one case of bacterial infection at the recipient site.

**Comments/implications for practice** The data on surgical procedures should be interpreted with caution, as they are derived mainly from small case series and only scarce comparative trials, with questionable designs and outcome measures.

### **Psychological therapy**

One RCT [71] compared cognitive-behavioral therapy with person-centered therapy and also with controls receiving no psychological therapy. A total of 45 participants were enrolled. The study did not assess any other outcomes of interest.

**Comments/implications for clinical practice** Studies that take into account the effects of treatments on the patients' quality of life and global health, from the patient's point of view, are needed.

## Key points

- A meta-analysis, one additional systematic review, and several subsequent RCTs showed that NB-UVB, psoralen plus UVA light (using sunlight or artificial light sources), and topical class 3 corticosteroids are effective in comparison with placebo in treating generalized and localized vitiligo.
- There is RCT evidence indicating that NB-UVB is at least as effective as PUVA in achieving repigmentation of treated lesions.
- RCTs have reported that concurrent topical calcipotriol potentiates the efficacy of PUVA, but not the efficacy UVB. However, the concurrent use of topical tacalcitol has been shown to increase the efficacy of NB-UVB.
- There is some RCT evidence that indicates that tacrolimus is as effective as topical clobetasol propionate in treating vitiligo, although no placebo-controlled trials were found. Evidence from one RCT indicates that topical pimecrolimus is not effective in treating vitiligo.
- There is scarce RCT evidence on the efficacy of melagenine, pseudocatalase, levamisole, and systemic antioxidant therapy.
- We found limited evidence of the effectiveness of surgical treatments for selected patients
- We found that treatments were evaluated mainly in the short term, with few comparative trials. The maintenance value of therapies and the assessment of patients' preferences, satisfaction, and quality of life have not yet been adequately addressed. Patient compliance is seldom reported in the studies.

## Background

### Definition

Melasma is an acquired increased pigmentation of the skin, characterized by grey–brown symmetrical patches, mostly on the areas of the face exposed to the sun, but occasionally on the neck and forearms [1]. Its clinical and histological presentation does not differ between men and women, apart from differences in the incidence (see below) (Figure 55.1).

### Incidence/prevalence

There are few studies showing the prevalence of melasma. A study conducted in Mexico [2] and another in Peru [3] found that melasma accounted for 4–10% of new dermatology hospital referrals. Melasma was found to be the third most common pigmentary disorder of the skin in a survey of 2000 black people at a private clinic in Washington, DC [4]. Melasma is thought to be more common in people of Hispanic origin who live in areas of high ultraviolet-light exposure, as well as in Asian people [5]. Melasma may also affect men, especially those of Hispanic or Asian origin.

### Etiology

Melasma occurs most commonly during pregnancy, and has also been associated with the use of oral contraceptives containing estrogens and/or progestogens, and with certain drugs such as hydantoin used as an anticonvulsant [6–8]. Sun exposure appears to be important for the development of melasma [9], and there also appears to be a familial predisposition [9]. On the basis of a small case series in Puerto Rico, sunlight exposure and family history appear to be the most important determinants for the development of melasma in men [10]. The exact cause of melasma is unknown; hormonal mechanisms may be involved. Mild ovarian dysfunction has been considered as a cause, after a study found increased levels of luteinizing hormone and low levels of serum estradiol in nine women with melasma [11]. A case–control study of 108 nonpregnant women with melasma found a significant association with increased thyroid antibodies in the blood [12]. Studies measuring

levels of immunoreactive  $\beta$ -melanocyte stimulating hormone found normal levels in patients taking oral contraceptives, some of whom had melasma [13], suggesting that the development of melasma is not related to melanocytic hormone.

### Prognosis

Melasma usually persists for several years. It may present as odd streaking on the face, causing cosmetic disfigurement, and can have a significant impact on the patient's quality of life [14]. Pregnancy-related melasma may persist for several months after delivery, and melasma related to hormonal treatments may persist for long periods after oral contraceptives have been stopped. Recurrences are common, particularly after repeat exposure to the sun [9]. The response to treatment can be variable, although dermal-type melasma is less responsive than the epidermal type (see below). The benefits of treatment may not be apparent for many months. Treatment is often unsatisfactory, and has been associated with side effects such as local irritation, scarring, contact dermatitis, and residual patches of lighter color on the skin – known as “confetti pigmentation.”

### Diagnostic tests

Melasma is a clinical diagnosis. Microscopy studies suggest that there may be two main types of melasma: the epidermal type, characterized by increased melanin pigmentation in the suprabasal layers of the epidermis; and the dermal type, characterized by increased melanin in the dermal macrophages, with associated milder epidermal hyperpigmentation [9]. This distinction may provide a clue to the expected treatment response. The dermal type has been found to be less responsive to conventional therapy [5]. An alternative way of establishing the type of melasma clinically is by using a source of ultraviolet A light, such as a Wood's lamp [15], in which the dermal type appears much darker than the epidermal type. Ultraviolet-light lamps enhance the lesions in light-colored skins (i.e., skin phototypes I–IV) [12], but may be of little use in dark-skinned people, in whom the enhancement is less prominent. This distinction may not be clinically relevant as most studies which

Figure 55.1 Patient with melasma.

perform this classification show the majority of these patients having epidermal or mixed-type melasma, with dermal melasma only present in 10% of patients [16]. This situation is further complicated by a study comparing clinical and histological examination by Grimes *et al.* which found that there was poor correlation between clinical examination with a Wood's light diagnosis of epidermal melasma and histological examination, as samples examined had increased melanin deposition in the epidermis and dermis [17].

### Aims of treatment

Treatments should aim to prevent the development of melasma, to prevent or reduce the severity of recurrence, to reduce the affected areas, improving the cosmetic defect, and to reduce the time to clearance, with the fewest possible side effects. The time to clearance is important, as current treatments take several months to have any effect.

### Relevant outcomes

- Improvement in patient satisfaction measures and quality-of-life assessment measures (Box 55.1) [14] during the time course of the intervention.
- Clearance of lesions as evaluated by objective methods; for example, the melasma area and severity index (MASI) or the melasma area and melanin index (MAMI) (Box 55.2) [18,19], or any other objective, semiquantitative measures of disease.
- Lightening of pigmentation (evaluated objectively by a colorimeter or a mexameter, for example).
- Adverse effects, such as irregular pigmentation or irritation related to the interventions.

### Methods of search

Medline (1966–April 2012), Embase (1980–April 2012) and the Cochrane Library were searched for the terms “melasma,”

#### Box 55.1 Melasma quality-of-life scale [14]

On a scale of 1 (not bothered at all) to 7 (bothered all the time), patients rate how they feel about:

- the appearance of the skin condition;
- frustration about the skin condition;
- embarrassment about the skin condition;
- feeling depressed about the skin condition
- the effects of the skin condition on interactions with other people (e.g., interactions with family, friends, close relationship);
- the effect of the skin condition on their desire to be with people;
- the skin condition making it hard to show affection;
- skin discoloration making them feel unattractive to others;
- skin discoloration making them feel less vital or productive;
- skin discoloration affecting the sense of freedom.

The melasma quality of life is scored from 7 to 70, with higher scores indicating a poorer melasma-related, health-related quality of life.

#### Box 55.2 Melasma scoring indexes

##### Melasma area and melanin index (MAMI) [18]

This is calculated in the same way as MASI (see below), but darkness and homogeneity are replaced by the single variable of the melanin index. This variable is a measurement of color at involved sites, determined using a reflectance spectrophotometer.

##### Melasma area and severity index (MASI) [19,20]

The index evaluates four areas of the face: the forehead (f), the right malar (rm) and left malar (lm) regions, and the chin (c). Each of the first three is weighted with 30% of the score, while the chin is weighted with 10% of the score. The extent of melasma in each area *A* is calculated and given a numerical value as follows:

0 No involvement

1 <10%

2 10–29%

3 30–49%

4 50–69%

5 70–89%

6 <90–100%.

The *severity* of the melasma is described by a combination of two factors, darkness *D* and homogeneity *H*, each evaluated on a scale of 0 to 4, and is calculated as follows:

$$\text{MASI} = 0.3(D_f + H_f)A_f + 0.3(D_{rm} + H_{rm})A_{rm} + 0.3(D_{lm} + H_{lm})A_{lm} + 0.1(D_c + H_c)A_c$$

where “f” is forehead, “rm” is right malar, “lm” is left malar, and “c” is chin.

“chloasma,” and “mask of pregnancy” as text words and/or key words if present in the database. Systematic reviews were searched for first, followed by randomized controlled trials (RCTs) using a filter; the remaining abstracts from the search were then scanned to see whether any RCTs had been missed using the search filter. References from identified papers were searched. The results of the search were appraised by at least two of the authors.

Categorization of studies: in most studies of melasma, sunscreens are used as a baseline measure with additional interventions. We have therefore not categorized them as combination studies. We

have used the term “combination study” when a combined effect of two or more interventions is assessed.

## Questions

### How effective are preventive interventions in high-risk populations?

#### Case scenario 55.1

A Latin-American woman is planning to have children and is concerned about developing melasma. Her three sisters all developed melasma during pregnancy, which lasted for many years.

#### Efficacy

We found no studies assessing the effects of preventive measures (such as educational interventions to avoid sun exposure or use of prophylactic sunscreens) in high-risk populations.

#### Comment

Overall, expert opinion supports interventions aimed at reducing exposure to ultraviolet light, which may reduce the risk of developing melasma.

#### Key messages

We found no good evidence to support preventive interventions in high-risk populations. Current opinion, based on known risk factors, suggests that preventing exposure to ultraviolet light such as sunlight may reduce the risk of developing melasma.

#### Implications for clinical practice/categorization

Unknown effectiveness.

### How effective are therapeutic interventions in childbearing, pregnant, and breastfeeding women who develop melasma?

#### Case scenario 55.2

A 30-year-old woman develops melasma in the 20th week of her first pregnancy. She is not on any medication and has not used an oral contraceptive in the past.

#### Efficacy

We found no studies in pregnant or breastfeeding women. Several studies did not clearly specify whether the women included were pregnant or became pregnant during follow-up. When components used in the study included those that are not recommended in childbearing women (i.e., retinoids), the study was considered to be done in nonpregnant or nursing populations and is discussed under the corresponding question.

#### Comment

Common expert opinion is that women with a high risk of developing melasma should avoid exposure to the sun or other sources of ultraviolet light. It would seem reasonable to consider the use of broad-spectrum sunscreen with solar protection factor (SPF) >30 in women who are at high risk of developing melasma.

#### Key messages

We found no good evidence to support any therapeutic intervention in childbearing, pregnant, or breastfeeding women. Current opinion suggests that such women with melasma may benefit from

using broad-spectrum sunscreens and avoiding exposure to ultraviolet light such as sunlight.

#### Implications for clinical practice/categorization

Unknown effectiveness.

### How effective are therapeutic interventions in non-childbearing women?

#### Case scenario 55.3

A 35-year-old woman presents with a 3-month history of melasma. She had been taking an oral contraceptive, which she had recently stopped taking after a tubal ligation. She is an outdoor worker.

#### Sunscreens

##### Efficacy

We found one systematic review [21]. We found one RCT [22] comparing sunscreens with placebo in women receiving hydroquinone. The study included 59 nonpregnant Hispanic women in Puerto Rico. None of the participating women was taking contraceptive hormones and all had had melasma for 2–25 years. All of the women were prescribed a clearing solution of hydroquinone 3% in hydroalcoholic solvent twice daily. The women were randomly assigned to a once daily morning application of broad-spectrum sunscreen or vehicle (placebo) and were then followed for 3 months. Improvement, assessed subjectively by a physician, was seen in 26 of 27 (96%) women receiving sunscreen and hydroquinone, in comparison with 21 of 26 (81%) women receiving placebo and hydroquinone (relative risk [RR], 1.19; 95% confidence interval [CI], 0.98–1.46). Improvement rates as assessed by participants were high in both groups: 27 of 27 (100%) with sunscreen and hydroquinone, in comparison with 25 of 26 (96%) with placebo and hydroquinone (absolute risk reduction [ARR], 4%; 95% CI, 1–18.9%). Six of the 59 (10%) women withdrew and nine of 53 (17%) women developed side effects of stinging and burning.

##### Comment

The side effects seen in the nine patients above were attributed to hydroquinone. It is unclear which arm this was in as both groups received hydroquinone.

##### Key messages

We found limited evidence from a single RCT evaluating the effect of therapeutic sunscreens. It showed that, during the 3-month follow-up period, the majority of women receiving hydroquinone improved regardless of the addition of sunscreen to their treatment. There was no detail, for example, of the SPF of the sunscreen or if participants could reapply the sunscreen during the day. The study also did not describe if women used other strategies to avoid sunlight. Sunscreens are commonly a co-intervention in studies on melasma and improvements seen in the placebo arm ascribed to the sunscreen co-intervention.

#### Implications for clinical practice/categorization

Unknown effectiveness.

#### Topical corticosteroids

##### Efficacy

We found one systematic review [21] and one trial of 17 participants (16 consecutive women and one man) followed for 3 months

[23]. The trial compared the topical application of a 0.2% betamethasone 17-valerate cream with cream excipient (placebo). Randomization was used to allocate the side of the face to which creams were applied. There was good improvement (subjectively defined by the physician and participants) in eight people, eight of whom considered betamethasone to be better than placebo. Three considered they achieved moderate improvement with either betamethasone or placebo, and four people said they had no improvement at all. One person withdrew from the trial.

### Drawbacks

The study reported no significant side effects [23].

### Comment

Although the study reports that betamethasone was effective as a depigmenting agent ( $P < 0.05$ ), the numbers were very small and seven of 16 patients found no therapeutic difference between treatment and placebo [23]. There is controversy over the balance between benefits and harms of using topical steroids in the treatment of melasma, especially since long-term use on the face can cause skin thinning and telangiectasia.

### Key messages

We found insufficient evidence to support the use of topical steroids in melasma. There is controversy over the use of topical steroids in melasma.

### Implications for clinical practice/categorization

Unknown effectiveness.

### Topical retinoids

#### Efficacy

We found one systematic review [21] and three RCTs.

**In Caucasian people** The first RCT was done in 50 Caucasian women with facial melasma (94% epidermal, 4% dermal, 2% mixed) [24]. The trial compared the daily use of topical 0.1% tretinoin with placebo (vehicle cream for tretinoin) over a period of 40 weeks. The withdrawal rate was 24%. At 40 weeks there was a significant difference and 13/19 in the tretinoin group were rated as “improved” or “much improved” compared with 1/19 in the placebo group ( $P = 0.0006$ ).

**In Asian people** The second RCT [18] included 30 Thai people (26 women and four men) with facial melasma. The RCT compared a titrated daily application of 0.05% isotretinoin gel with a color-matched vehicle used as placebo, for 40 weeks. There were no significant differences in the MASI or MAMI scores in the evaluations done at 2 weeks, 4 weeks, and monthly for up to 40 weeks. The only two participants with dermal melasma were allocated to the isotretinoin group. Participants in both groups improved during the 40-week follow-up.

**In black people** One RCT in the USA compared the daily application to the entire face of a cream with 0.1% tretinoin or placebo (vehicle) in 30 Afro-Americans (29 women), followed for 40 weeks [19]. The MASI score was used to assess the severity of melasma. Darkness and homogeneity were also assessed. Colorimetry, photographic, and histology studies were carried out before and after

treatment. After 40 weeks, there was a mean reduction in the MASI score by 32% compared with a mean reduction in the placebo group by 10% ( $P = 0.03$ ). The significant improvement noted on the subjective MASI evaluation was also confirmed on colorimetry. This improvement, however, was not seen on all measures. Patients were also assessed by an independent clinician, who found no significant differences between tretinoin and placebo after 24 weeks – improved or much improved: 11 of 15 (73%) with tretinoin, compared with six of 13 (46%) with placebo (RR, 1.6; 95% CI, 0.8–3.1).

### Drawbacks

**In Caucasian people** In the first RCT, 12 participants were lost to follow-up. One of the causes for withdrawal was adverse events in the tretinoin group: three of 25 (12%) versus none of 25 with placebo. Worsening of melasma occurred in a woman in the tretinoin group. Moderate cutaneous reactions were more frequent with tretinoin (22 of 25; 88%) than with placebo (seven of 24; 29%; RR, 3.0; 95% CI, 1.6–5.7). The number needed to harm (NNH) was 1.7 (95% CI, 1.3–3.1). Severe cutaneous reactions occurred only with tretinoin (four of 25; 16%; NNH, 6.3) [24].

**In Asian people** The second RCT found similar withdrawals rates in both groups: four of 15 (27%) with isotretinoin, in comparison with three of 15 (20%) with placebo [18]. Mild transient erythema and/or peeling occurred only in the isotretinoin group (four of 15; 27%; NNH, 3.8), which resolved after 4 weeks.

**In black people** The most frequently found side effects in the third RCT were erythema and/or peeling in the area of application: 10 of 15 (67%) with tretinoin, in comparison with one of 15 (7%) with placebo (RR, 10; 95% CI, 1.5–68.7; NNH, 1.7; 95% CI, 1.1–2.4) [19].

### Comment

The withdrawal rate was high in the first RCT on Caucasian patients and there was no intention-to-treat analysis [24]. All three RCTs have small samples, and are inconclusive as a result. The RCT on black patients showed no significant improvement on the scale of “much worse” to “much improved,” but when the MASI scores were analyzed a significant difference was detected [19]. Side effects were quite common in people receiving retinoids.

### Key messages

We found some evidence of an effect of retinoids in people with melasma, and more so in Caucasian patients with a higher proportion of epidermal melasma over black patients with dermal melasma. No beneficial effect was observed with topical isotretinoin, a chemically related structure to tretinoin.

### Implications for clinical practice/categorization

Tretinoin may be beneficial.

### Azelaic acid

#### Efficacy

We found one systematic review [21] and three RCTs.

The first RCT [25] was a prospective, single-blinded study in 30 Indian patients (25 females, five males) that compared 20% azelaic acid (AZA) versus 20% AZA and 0.05% clobetasol propionate used sequentially. This was a left-to-right comparative study, with 20% AZA used on one side for 24 weeks, in comparison with 8 weeks

of topical steroid followed by 16 weeks of 20% AZA. Clinical evaluation, photographic controls, and an assessment for overall response were done at 4, 8, 16, and 24 weeks. Evaluations done at 4-weekly intervals showed improved outcomes at 16 weeks with sequential therapy in comparison with 20% AZA alone ( $P > 0.001$ ). However, at week 24, both groups showed good to excellent responses.

We found two RCTs [26,27] comparing AZA with hydroquinone. The first compared 20% AZA with 2% hydroquinone [28] and the second with 4% hydroquinone [26]. Most studies of hydroquinone have used the 4% strength, and the study using 2% hydroquinone did so as there were ethical obstacles to using placebo. The first RCT [28] was in 340 patients with epidermal or mixed melasma (including 17 men) comparing twice-daily 20% AZA cream with twice-daily 2% hydroquinone cream for 24 weeks. It found that improvement (defined as a reduction of  $>50\%$  in a score including area and pigmentation) was higher with AZA (106 of 154; 69%) than with hydroquinone: 88 of 161 (55%) (RR, 1.26; 95% CI, 1.06–1.50), number needed to treat (NNT) 7 (95% CI, 4–30). The majority of patients were of skin phototypes III–VI. However, no statistical difference between the groups was found on the objective measures of reduction in lesion size. The second RCT [26] was on 329 South American women with epidermal or mixed melasma comparing twice-daily 20% AZA cream with twice-daily 4% hydroquinone cream for 24 weeks. There was no significant difference in the two groups with regard to overall response or reduction in pigmentary intensity. Both subjective and objective assessments were made. Using the participants who had good to excellent response as “treatment success,” 71.9% of those in the hydroquinone group had success versus 64.8% in the AZA group.

### Drawbacks

The RCT [25] comparing sequential therapy of AZA and topical steroids found little difference in adverse events between the groups. Five patients in the AZA group suffered mild irritation, while six patients in the sequential therapy group suffered mild acneiform eruptions. Sequential treatment produced faster improvement at 16 weeks, though there was no significant difference between the two groups at 24 weeks.

In both the comparison RCTs with hydroquinone, side effects were more frequent with AZA. In the first comparison RCT [28], mild adverse events including itching, burning, and erythema were reported in 61/147 in the AZA group and 22/153 in the hydroquinone group (RR, 3.0; 95% CI, 1.7–4.7; NNH, 4; 95% CI, 3–6). Marked irritation was more frequent with AZA (15 of 167; 9%) than with hydroquinone (two of 173; 1%; RR, 7.8; 95% CI, 1.8–33.5; NNH, 12; 95% CI, 7–30).

In the second RCT [26] most of the side effects were mild and transient, occurring more frequently in the AZA group (18/122) versus the hydroquinone group (1/121).

### Comment

The two studies [26,28] comparing AZA and hydroquinone reached different conclusions, and this is likely to be secondary to the different hydroquinone concentrations. There was a large loss to follow-up (86 participants out of 329) in the RCT comparing AZA with 4% hydroquinone [26], though the differential loss to follow-up between the groups was not significant. No intention-to-treat analysis was used. The use of topical steroids was associated with faster clearance, but has to be evaluated for side effects in larger studies.

### Key messages

We found some evidence for the use of AZA, which was found to be superior to 2% hydroquinone in achieving improvement. We found no difference when AZA was compared with 4% hydroquinone. AZA was associated with a higher incidence of side effects. When used sequentially with AZA, topical steroids may result in faster improvement of melasma.

### Implications for clinical practice/categorization

May be beneficial.

### Hydroquinone

#### Efficacy

We found one systematic review [21] and two RCTs. The first RCT [29] was done between autumn and spring in Brazil (48 patients, four men; age range 19–55 years). The trial compared a cream containing 4% hydroquinone and two sunscreens of SPF 15 with a cream containing two sunscreens of SPF 15, both applied for 12 weeks. In addition, participants applied an SPF 30 sunscreen every morning; no explanation was given for the need of three different sunscreens in each arm. Outcomes were assessed by subjective clinical evaluation and photography. After 12 weeks, hydroquinone showed higher improvement rates (20 of 21; 95%), in comparison with 16 of 24 (67%) with placebo (RR, 1.4; 95% CI, 1.06–1.9; NNT, 3.5; 95% CI, 1.9–12.1). Total clearance of lesions was more frequent in patients receiving hydroquinone (eight of 21; 38%) in comparison with placebo (two of 24, 8%; RR, 4.6; 95% CI, 1.1–19.2; NNT, 3.4; 95% CI, 1.8–12.7).

A second RCT [30] randomized women's hemifaces to receive once-daily 5% ascorbic acid versus once-daily 4% hydroquinone in 16 women with melasma in Mexico. All participants were also instructed to apply a sunscreen every 3 h in the day. The women were evaluated every 4 weeks using digital photography, colorimetry, and subjective assessment: mild ( $<25\%$ ), moderate (25 to  $<50\%$ ), good (50 to  $<75\%$ ) and excellent ( $>75\%$ ). The women rated clearance better in the hemiface that received hydroquinone, at 93% (good to excellent) versus 62.5% (good to excellent;  $P < 0.05\%$ ). No significant differences were found between the treatments in the colorimetry evaluation.

We found two RCTs comparing hydroquinone with AZA (see above) [26,28].

### Drawbacks

The first RCT [29] found no difference in tolerability between the groups. Adverse events, mostly erythema, were reported in six of the 21 of those in the hydroquinone and sunscreen group versus five of the 24 in the sunscreen-only group (RR, 1.37; 95% CI, 0.49–3.85). In the second RCT [30], irritation was more frequently seen in the side that received hydroquinone (irritated hemiface: 11 patients with 4% hydroquinone versus one patient with 5% ascorbic acid).

### Comment

Hydroquinone (4%) plus sunscreen was found to be superior to placebo plus sunscreen [29]. The difference between treatments was stated to be statistically significant, though it is unclear which category of improvement was analyzed (“total” or “partial improvement” categories). Outcomes were not reported in five patients. The second study found that 4% hydroquinone was superior to 5% ascorbic acid on the patients' subjective assessments, but this improvement was not seen with objective colorimetry assessment [30].

### Key messages

We found evidence from one RCT showing that the use of hydroquinone plus sunscreen was superior to the use of sunscreen and placebo. We found limited evidence of the efficacy of 4% hydroquinone over 5% ascorbic acid. Although no significant difference was found on colorimeter assessment, the participants who self-assessed favored hydroquinone.

### Implications for clinical practice/categorization

May be beneficial (when used with sunscreen).

### Acid peels

#### Efficacy

We found one systematic review [21] and eight RCTs.

The first RCT [31] was a small split-face study of 10 participants in Singapore (skin phototypes IV or V), suffering moderate to severe epidermal melasma. This split-face study compared glycolic acid (GA) peels (concentration 20–70% increased according to tolerability) applied every 3 weeks to one side of the face with GA and hydroquinone cream applied twice daily for 24 weeks to both sides of the face. All participants also had a pretreatment of twice-daily 8% alpha hydroxy acid skin smoothing cream for 2 weeks. An independent evaluator assessed the results using a Munsell color chart and photographs. Participants also assessed the results. The physician evaluation found improvement on the side using peeling in all cases, and improvement in control sides in eight of 10 cases.

The second RCT [32] was in 40 patients in Pakistan (30 women and 10 men, aged 21–45, with phototypes IV–V, with melasma). They were randomly divided into two groups of 20 each. They all had six fortnightly facial peeling sessions with increasing concentrations of salicylic acid (first two sessions with 20% and subsequently with 30%). Group I was also treated with 4% hydroquinone cream for the subsequent 3 months, but group II had no additional treatment. Both groups used broad-spectrum sunscreens. Evaluations were made before and after finishing treatment, including a MASI score, photographs, and lesion size. The use of chemical peelings with salicylic acid showed significant improvement in both groups ( $P < 0.05$ ). After an additional 3 months of treatment with 4% hydroquinone cream, 80% of the patients in group I were reported to have continued significant improvement, in comparison with 50% of those in group II ( $P < 0.05$ ).

The third RCT [33] was a split-face trial on 21 Hispanic participants with moderate to severe epidermal or mixed melasma in Texas, USA. Patients were randomized to receive either 4% hydroquinone cream or 4% hydroquinone cream and 20–30% GA peels every 2 weeks applied to either the right or left side of the face for 8 weeks. Eleven of 18 participants felt there was more improvement on the peeled side versus 4/18 on the nonpeeled side. One of the patients felt there was no difference between the sides. In this RCT, physicians assessed improvement with subjective and objective measures. While there was a significant improvement from baseline in both groups, there was no significant difference in improvement in MASI scores or objective mexameter readings.

The fourth RCT [34] was a trial to compare Jessner's (14% salicylic acid, 14% lactic acid, 14% resorcinol in alcohol) peel with 30% salicylic acid peel after 2 weeks priming with 0.05% tretinoin cream nightly. Sixty participants with epidermal melasma were randomized to receive either Jessner's peel or salicylic acid peel for 5 min every 2 weeks for 12 weeks. There was a subsequent 12-week follow-up period. The authors found no statistically significant dif-

ference between the groups in terms of reduction of MASI at 12 weeks or 24 weeks.

The fifth RCT [35] was a split-face trial on 16 Korean patients (skin type III or IV) with mixed melasma confirmed on Wood's lamp analysis. Both sides of the face were treated for six sessions at 1 week intervals with a Q-switched 1064 nm laser (MedLite C6; Hoya ConBio, Fremont, CA, USA) (6 mm spot size, fluence 2–2.3 J/cm<sup>2</sup> at 10 Hz). In addition, one side of the face was randomly allocated to receive three sessions of 30% GA at 2 week intervals immediately after laser therapy. All patients were given a broad-spectrum SPF 50 sunscreen. Both objective and subjective assessments were performed. At the completion of the sixth laser treatment the peeled side had a 32.6% reduction in melanin index from baseline versus 22.0% reduction in the laser only side ( $P < 0.05$ ). This significant difference was also noted on the modified MASI (calculated to account for a certain portion of the malar area), where the physicians recorded a 37.4% reduction in the modified MASI in the peeled side versus 16.7% in the laser-only side. There was also a 5-month follow-up period, and 75% of patients on the combined peel and laser therapy rated their treatment as good or excellent versus 38% on the laser-only side.

The sixth RCT [36], a right–left comparison study, evaluated the effect of GA solution (Glycolic Acid Peels, NeoStrata, Princeton, NJ) and amino fruit acid (AFA) gel (AFA Peels, exCel Cosmeceuticals, Bloomfield Hills, MI) on Turkish patients (skin types II, III (79%) and IV) with epidermal-type melasma determined with a Wood's lamp. Thirty-one patients received 12 serial peels at 2-week intervals for a period of 6 months with GA on one side and AFA peels on the other side of the face. Contact time (2–6 min) and concentration (20, 35, 50, 70% GA; 20, 30, 40, 50, 60% AFA) was gradually increased depending on tolerability. Patients used broad-spectrum sunscreen (SPF 30) and practiced strict sun avoidance during the treatment period. At baseline and months 3 and 6 a modified MASI score was performed, alongside cutaneous tolerability assessments during and after peeling sessions and patient preference tests at the end of the study period of 6 months. A significant reduction of modified MASI score ( $P > 0.05$ ) was found at 6 months with both peeling methods. (GA:  $4.66 \pm 3.33$  to  $2.937 \pm 2.10$ ; AFA:  $4.237 \pm 3.22$  to  $2.547 \pm 2.05$ ) When comparing the two peeling methods, however, the authors found no significant difference between end of treatment modified MASI scores or patients' preference tests regarding melasma improvement (GA: 45.8%; AFA: 41.7%; same: 12.5%) or choice for future treatment (GA: 41.7%; AFA: 54.27%; same: 4.2%).

The seventh prospective, randomized study [37] compared the efficacy of Jessner's solution versus trichloroacetic acid (TCA) 20% solution versus concomitant use of hydroquinone 2% and kojic acid 2% as two separate products applied together. Forty-five female patients (skin types III, IV) with epidermal and mixed melasma (identified with Wood's light) had been randomized in three groups. After 2 weeks' priming with retinoic acid 0.05% daily, groups A and B received chemical peeling with either Jessner's solution or TCA 20% weekly for six sessions. Group C used hydroquinone 2% and kojic acid 2% as two separate products applied together at night for 8 weeks. The study was carried out in winter and all patients used SPF 45 sunscreen. Outcome was measured using the MASI score detected by a blinded investigator. At baseline, MASI score showed no significant difference between the three different groups and was as high as 13.660, 12.207, and 14.5 respectively in groups A, B, and C. The MASI score decreased significantly in each group ( $P < 0.001$ ) at week 8. After a follow-up period of 16 weeks, the MASI scores

were raised in each group compared with week 8, but they were still significantly lower ( $P < 0.001$ ) than baseline. Comparing the three different groups, at week 8, the MASI score was significantly lower in group A (Jessner's) and group B (TCA) than group C (hydroquinone and kojic acid), but there was no significant difference between groups A and B. After the 16-week follow-up period the MASI score stayed significantly lower ( $P < 0.001$ ) than baseline, but there was also a statistically significant difference between each group, with group B being the lowest and group C the highest.

The eighth RCT [38] compared application of 4% hydroquinone with a combination of 4% hydroquinone and 20–30% salicylic acid peels. This study was on 20 Latin American females of skin types III–V. The study design was of split face and the comparison was done by narrowband reflectance spectrometry. There were a total of four peels done 2 weeks apart. The study period was 8 weeks. The authors did not find any significant differences between the two sides of the face.

### Drawbacks

All of the participants in the first RCT [31] experienced stinging and redness post-peel, which was transient. One person had a burn after the 20% GA peel, resulting in hyperpigmentation, which cleared in 2 months. No side effects in the nonpeeled group were mentioned in the text.

In the second RCT [32], minor side effects were seen in most of the patients, such as mild burning, irritation, and stinging. No information is available about three patients who did not finish the treatment.

In the third RCT [33], four participants developed significant erythema, though no peeling or erosions occurred secondary to peels. There was no comment on adverse events from hydroquinone.

In the fourth RCT [34], eight of the 34 participants had excessive crusting versus 10/26 in the salicylic acid group (four crusting, two sunburn, two pigmentation, and two acneiform eruption) (RR, 1.63; 95% CI, 0.75–3.55).

In the fifth RCT [35], limited detail (no numbers presented) of adverse events was provided. Side effects were stated to be transient and mild, including erythema, burning, and desquamation.

In the sixth RCT [36], three patients developed vesicles, crusting, and erosions on the GA-treated site, and no side effects were observed with AFA applications. The authors stated that tolerability of AFA was better, resulting in an overall greater application in higher concentration during the 12 sessions.

In the seventh study [37] there were no drop-outs during the 8 weeks' treatment and the 16-week follow-up period. Transient side effect (<2 weeks) with post-peeling erythema occurred in 30% of patients treated with Jessner's solution and 20% of patients treated with TCA. Discomfort was reported in 25% in both groups. Hyperpigmentation developed in 1/15 patients treated with Jessner's solution and 3/15 in the TCA group. No side effect was reported in the third group treated with hydroquinone and kojic acid.

In the eighth RCT [38], limited detail (no numbers presented) of adverse events was provided. Side effects were stated to be transient and mild, including erythema, burning, and desquamation. This study was limited to four salicylic acid peels and over a short period of time of 8 weeks.

### Comment

The first RCT may have been too small to rule out differences, and concealment may have been difficult to achieve because of the side

effects of the peelings [31]. The second RCT [32] has methodological flaws. There is no description of inclusion or exclusion criteria, methods of randomization, or description of concealment. Further evaluation in long-term studies with better methodological quality is necessary to evaluate side effects and recurrences.

In the third RCT, two of the 21 participants did not complete the global evaluation and the data presented were incomplete. There is also no clear record of the side effects from hydroquinone [33].

In the fourth RCT, only patients with epidermal melasma were included. There were three withdrawals at 12 weeks and 14 withdrawals (23.2%) at 24 weeks. No intention-to-treat analysis was performed [34].

In the fifth RCT [35] the baseline characteristics were not provided for each group, though it was noted there was no significant difference in the relative lightness index between the two sides of the face. Adverse events were reported in minimal detail, with a further statement that no new adverse events were noted. It is unclear if these were not recorded if the authors felt it was a known side effect of peels or lasers.

In the sixth RCT [36] only a small number of patients with epidermal melasma were included. The investigators followed an individualized treatment regime with different application times and concentrations which resulted in better tolerability, but it might have influenced overall outcomes. No follow-up was carried out after the 6-month treatment period.

In the seventh study [37] the authors found that TCA might be superior to Jessner's solution and hydroquinone applied with kojic acid in the long term, as relapse rate was lower in this group. However, a higher rate of postinflammatory hyperpigmentation occurred in this group. It is not clear if hyperpigmentation influenced the assessment of the MASI score in the TCA group.

The eighth RCT [38] is limited by a small number of participants and by the fact that only four peels were done in each patient.

### Key messages

We found insufficient evidence to assess the effects of acid peels, as a variety of concentrations and formulations were used in each study. Only two RCTs compared two different peels. These trials found no significant difference either between Jessner's and 30% salicylic acid peels or comparing GA with AFA peels. GA peels did not enhance the effect of hydroquinone cream as similar effects were noted with use of hydroquinone cream alone. Additionally, GA peels did not enhance the lightening effect when combined with hydroquinone and GA cream. GA peels did enhance the lightening effect of Q-1064nm laser in one RCT. This effect was maintained over the 5-month follow-up period, though a slight deterioration was noted. There was limited evidence of effectiveness of salicylic acid peels from one RCT, which showed significant improvement in the treated groups from baseline, the effect of which was augmented with 4% hydroquinone. This study had limitations. Studies with longer follow-up periods and better methodological qualities will be required. In the former three RCTs, increased adverse events were noted on the peeled side.

### Implications for clinical practice/categorization

Unknown effectiveness.

### Combined therapies

#### Efficacy

We found one systematic review and 11 RCTs. The first trial was an open RCT (50 Asians, 49 women, with nondermal melasma and

not taking oral contraceptives) [20]. It compared the daily use of a cream containing 20% AZA, 0.05% tretinoin, and sunscreen, with a cream containing 20% AZA and sunscreen, for a period of 6 months with monthly evaluations. The number of withdrawals was high and it is therefore difficult to draw conclusions. In addition, some outcome categories overlapped.

A second RCT [39], including 65 dark-skinned people with skin phototypes >III, with hyperpigmentation, 44 of whom (68%) had melasma, compared a cream containing 20% AZA cream plus 15–20% GA (first month only) plus sunscreen with 4% hydroquinone plus sunscreen; the participants were followed for 24 weeks. There was no difference between the two groups with regard to overall improvement, and the reductions in lesion area, pigmentary intensity, and disease severity were comparable in the two treatment groups.

A third RCT [40] was conducted on 40 Chinese women with pure epidermal melasma, confirmed by Wood's lamp (age range not specified), comparing a twice-daily application of a gel containing 2% kojic acid, 2% hydroquinone, and 10% GA followed by a sunblock with titanium dioxide SPF 15 with a twice-daily application of a control gel containing 2% hydroquinone and 10% GA, followed by sunblock with titanium dioxide SPF 15. Randomization was used to determine which side of the face would receive each intervention. The frequency of >50% clearance of the melasma area was greater on the kojic acid side, although the difference was not significant: 24 of 40 (60%) for the gel containing kojic acid, versus 19 of 40 (48%) for the combined gel without kojic acid (RR, 1.3; 95% CI, 0.8–1.9). When the participants assessed improvement, it was found to be better with the gel containing kojic acid.

The fourth RCT [41] included 38 women with skin phototypes I–IV and melasma (type not specified). The study randomized affected areas of skin instead of people, and randomization was carried out using a list. The study compared a cream containing 12% alpha hydroxyl acid (particular preparation not specified), 1% polypeptide ascorbate complex, and titanium oxide photoprotector with a preparation containing titanium oxide photoprotector and the vehicle for the cream prepared to the same pH. On the patients' global assessment, measured using a visual analogue scale (VAS) for area and pigmentation, more women receiving the active treatment improved than those using placebo. However, the difference did not quite reach significance; 34 of 36 (94%) with the combination treatment versus 17 of 36 (47%) with the placebo (RR, 1.51; 95% CI, 0.96–2.40). Differences were significant for the melanic index, measured using a mexameter (mean melanic index 15.2 with the active treatment versus 22.1 with placebo;  $P < 0.01$  at day 56).

The fifth RCT [42] (39 patients with facial melasma, 5% of whom had dermal melasma under Wood's light; 38 women, followed for 3 months) compared 2% hydroquinone and 5% GA gel with 2% kojic acid and 5% GA gel. This study compared interventions applied to the left or right side of the face. Outcomes involved a comparison of facial photographs taken using an ultraviolet filter, clinical evaluation, participants' impressions, and the decrease in the affected area (no formal scales were used). There were no significant differences between the groups (28% reduction with kojic acid and 21% reduction with hydroquinone).

The sixth RCT [43] compared 4% hydroquinone cream plus 10% buffered GA, plus vitamins C and E plus sunscreen (compound cream, concentrations of vitamins C and E unspecified) versus sunscreen cream alone over a period of 12 weeks in 39 Hispanic women with epidermal melasma, skin types III–V, aged 18–50 years. Improvement in pigmentation was assessed objectively using the

mexameter and subjectively with MASI assessments. There was a significant decrease in the mexameter readings ( $P < 0.0001$ ) and reduction in MASI ( $P < 0.01$ ) using the combination cream compared with sunscreen alone. However, the patients' global evaluation showed moderate, obvious, or marked improvement in 19 of 20 women (95%) using the combination cream and 13 of 15 (87%) with sunscreen alone.

The seventh study [16] was a multicenter trial that included 641 patients who were randomly assigned to receive either tretinoin 0.05% (RA), hydroquinone 4.0% (HQ), and fluocinolone acetonide 0.01% (FA) (RA+HQ+FA) in a hydrophilic cream base; or (RA+HQ) or (RA+FA) in the same vehicle cream. A baseline photograph, an eight-point scale for investigator assessment of global improvement, and a melasma severity rating score (0–4) were used. The patient population consisted predominantly of white women, with skin types I–IV. The patients included had had melasma for at least 3 months and had a melasma severity of at least 2 on the melasma severity score. The end point of the study was the proportion of patients achieving complete clearance at 8 weeks. A secondary end point was the proportion of patients achieving complete or near-complete clearing (severity rating score: 0). At 8 weeks, the authors found that 26.1% of the patients were completely cleared with RA+HQ+FA, in comparison with 9.5% with RA+HQ, 1.9% with RA+FA, and 2.5% for HQ+FA ( $P < 0.001$ ). Complete clearing or near-complete clearing was achieved in 77% of patients in the RA+HQ+FA group, in comparison with 42.2% for HQ+FA, 27.3% for RA+FA, and 46.8% for RA+HQ ( $P < 0.001\%$ ).

The eighth RCT [44] was a multicenter trial in nine centers in South East Asia on 260 participants who were randomized to triple-combination (RA+HQ+FA) cream or 4% hydroquinone cream for 8 weeks. Participants assessed self-improvement using a static global assessment score. A score of 0 related to clear and 1 related to minor hyperpigmentation. Significantly more participants in the triple-combination group (87/125) compared with the 4% hydroquinone group (57/129) achieved a score of 0 or 1 (RR, 1.58; 95% CI, 1.26–1.97). This significant difference was also noted in the physician assessment. In this trial the participants' overall satisfaction with treatment was assessed by means of a questionnaire. Significantly more participants (71%) in the triple-combination group versus 50% in the hydroquinone group were satisfied or very satisfied (trial authors report  $P = 0.005$ ).

The ninth RCT [45] was a comparison between triple-combination cream (TCC) and nonablative 1550 nm fractional laser therapy and is reported in the laser therapy section.

The tenth RCT [46] evaluated the safety and efficacy of serial GA peels in combination with topical AZA 20% and adapalene 0.1% gel versus treatment with AZA 20% and adapalene 0.1% only on 28 patients (one man) with epidermal melasma (by Wood's lamp examination) for a treatment period of 20 weeks. The chemical peel group (16 patients) received eight GA peels (Glycolic Acid Peel Solution, Neostrate) every other week for 3–5 min with a gradually increasing concentration of 20–35–50–70%, combined with AZA 20% cream b.d. (Skinoren cream, Schering Pharmaceuticals, Turkey) and adapalene 0.1% gel o.d. (Differingel, Liba Pharmaceuticals, Kavacik, Istanbul, Turkey) for 20 weeks. The control group (12 patients) used only AZA cream and adapalene gel without chemical peeling. The MASI score was obtained at baseline and every 4 weeks. A significant decrease of the MASI score was found in both groups, with an 83.08% ( $P < 0.001$ ) change in the chemical peel group and a 69.34% ( $P < 0.005$ ) decrease in the control group. When comparing the two treatments, a significant difference was found in favor

of the peel group at week 12 ( $P = 0.013$ ), 16 ( $P = 0.035$ ), and 20 ( $P = 0.0048$ ).

The eleventh RCT [47], an open-label trial on 120 patients from four centers in Brazil compared the effect of a TCC (hydroquinone 4%, tretinoin 0.05%, flucinolone acetonide 0.01%) daily with hydroquinone 4% (HQ: Claripel™ Stiefel Laboratories INC., Miami FL) b.d., used for 8 weeks. Both groups applied SPF 30 sunscreen at least once a day. Every 2 weeks the investigators evaluated melasma severity using a 0–3 scoring system (0: lesion very similar to the surrounding skin; 3: markedly darker) and overall improvement using a 5 to –1 score (5: 100% clearance; –1: worsening). Primary success was defined as score 0 at week 8; secondary success was an improvement score 3–5 ( $>75\%$  improvement). Patients performed an end-of-treatment overall evaluation using a scale 4 (excellent) to 1 (poor). In the TCC group, melasma score was significantly lower at weeks 4, 6, and 8 ( $P < 0.003$ ). Primary success was achieved for 35% of the TCC group versus 5.1% of the HQ group ( $P < 0.0001$ ); secondary success was achieved for 73% of TCC and 49% in HQ. Treatment rated as excellent was 50% for TCC and 34% for HQ.

### Drawbacks

The reasons for withdrawals in the first RCT [20] are not clear. Numbers were similar in the two groups: six of 25 (24%) in the AZA, tretinoin, and sunscreen group versus seven of 25 (28%) in the AZA and sunscreen group (RR, 0.9; 95% CI, 0.3–2.2).

In the second RCT [39] the AZA group experienced significantly more burning and peeling. There were two withdrawals in the AZA group and four in the hydroquinone group. However, these were described as not being due to side effects of the preparations.

All participants in the third RCT, comparing a combination of hydroquinone and GA followed by sunblock with or without 2% kojic acid [40], complained of redness, stinging, and mild exfoliation on both sides of the face. These adverse events settled by the third week of the study. No further details were provided. Three women withdrew from the study because of adverse effects on both sides of the face, and were replaced by three other women.

In the fourth RCT comparing alpha hydroxyl acid, polypeptide ascorbate complex, and titanium oxide photoprotector with a preparation containing titanium oxide photoprotector [41], one woman withdrew after 28 days because of depigmentation. However, no detail is provided on whether this happened on the intervention or control cheek. A second participant was excluded when it became apparent that she did not have melasma. In the active treatment group, a higher frequency of erythema and a burning sensation was reported, and this persisted throughout the follow-up period. However, no further details are provided.

In the fifth RCT [42], both treatments were described as being well tolerated, although all participants had some degree of skin irritation. Kojic acid gel was found to be a stronger irritant. No further details are provided.

In the sixth RCT, all the side effects reported were either mild or moderate and included burning, itching, dryness, redness, and peeling. No serious side effects were seen [43].

In the seventh RCT [16], a total of 387 of the 642 patients suffered side effects such as erythema, desquamation, burning, dryness, and pruritus, but these were considered to have been related to the study drugs in only 16 of the patients. In the results section, percentages are used instead of numbers of patients, and no description of –outs is given. Only one patient receiving HQ+FA suffered from skin atrophy. The authors suggest a protective effect of retinoids as a possible mechanism.

In the eighth RCT [44], adverse events were significantly more frequent in the triple combination groups compared with hydroquinone (RR, 3.55; 95% CI, 2.23–5.65). The most commonly reported side effects were erythema, irritation, and discomfort of the skin, though this was stated to be mild in intensity.

In the tenth RCT [46], mild burning and itching were reported with the AZA cream which resolved within a few weeks. No side effect was noted with the adapalene cream. Three patients experienced moderate to severe epidermolysis after the GA peel, requiring treatment with topical bethamethason valerate 0.1% cream for 7 days.

In the eleventh study [47], one drop-out was reported from the HQ arm due to a non-drug-related adverse event. Erythema, burning sensation, and desquamation were reported as the most frequent side effects in both groups, with no significant difference between the two arms. At week 8, facial telangiectasia occurred in 15% of the TCC group and in 9% of the HQ group (no  $P$  value provided). Systemic side effects were also reported in both groups, the most frequent being headaches (TCC: 11; HQ: 9).

### Comments

Methodological limitations, such as high withdrawal rate, compromise the validity of the results in the first RCT comparing AZA, tretinoin, and sunscreen with AZA and sunscreen [20].

In the second RCT, comparing AZA cream, GA, and sunscreen with hydroquinone and sunscreen, it was not possible to determine if the response varied between people with melasma and people with other hyperpigmentation conditions [39]. It is therefore difficult to draw valid conclusions.

The third RCT, comparing a gel containing kojic acid, hydroquinone, and 10% GA followed by titanium dioxide sunblock with a gel containing hydroquinone and GA followed by titanium dioxide sunblock had a small sample size which may have been insufficient to rule out an effect [40]. Other limitations include the lack of detail on allocation concealment and the lack of objective measures of improvement.

The fourth RCT [41] did not provide details on the melasma type. Melasma type has been associated with treatment response. The study does not give details of the kind of alpha hydroxyacid used and lacks details of demographic data.

The fifth RCT does not allow one to look at variables, but gives percentage improvements and  $P$  values. It concludes that the addition of 2% kojic acid gel to GA is as efficacious as 2% hydroquinone [42]. The addition of 2% kojic acid to a gel containing 10% GA and 2% hydroquinone further improves melasma. No additional side effects were reported on the kojic acid side [40].

The sixth RCT [43] found that the improvement seen with the compound cream on the patient assessed results was much less marked compared with physician subjective MASI reduction or mexameter results. No explanation is provided for this. Additionally, four women were lost to follow-up and it is unclear which group this is from.

The seventh RCT [16] has some methodological drawbacks. The publication combines the results of two separate studies, and the authors do not provide any details of these studies. The randomization methods are not clear. The results section only provides percentages, and there is no mention of drop-outs.

The eighth RCT [44] had patient and physician assessments as well as quality-of-life scores. Intention-to-treat analyses was performed. However, there were no objective measures of improvement.

In the tenth the study small sample size provides only weak evidence to support the superior effect of GA peels in combination with AZA and adapalene [46]. The study does not give details of variables, but lists only *P* values and mean value of improvement. Side effects were only mentioned with the use of AZA, although it was applied in combination with adapalene [46].

In the eleventh RCT [47] the type of melasma is unknown. No objective data analysis was performed, but a subjective scaling system was used to measure outcomes.

### Key messages

A variety of combination creams was used. Some studies had significant methodological flaws that compromised the validity of the results, including small sample sizes or lack of objective measures. There was limited evidence for each cream as each formulation was unique and studied in one RCT each except the TCC (RA+HQ+FA) in three RCTs. The TCC was more effective than any of the agents in dual combination. The TCC was also shown in another two RCTs to be more effective than 4% hydroquinone alone. A different formulation of the triple-combination cream with a higher percentage of hydroquinone (hydroquinone 5%, tretinoin 0.05%, triamcinolone acetonide 0.1%) was used in another RCT and found to be equally effective to laser therapy with a nonablative fractional laser (reported below).

### Implications for clinical practice/categorization

TCC may be effective.

### Laser therapies

#### Efficacy

We found one systematic review [21] and seven RCTs.

The first RCT [48] included eight dark-skinned people (skin phototypes IV–VI) with dermal melasma diagnosed using a Wood's lamp. The article does not provide any details of the participants' demographic data. All of the participants received a 14-day course of 0.05% tretinoin cream, 4% hydroquinone cream, and 1% hydrocortisone cream, applied twice daily. They were asked to use a sunblock of SPF 15 or higher. The participants had a 1 cm<sup>2</sup> area of the face exposed to one pass of the 950µs pulsed carbon dioxide laser, with a computerized pattern generation set at 300 mJ/cm<sup>2</sup>. The intervention group received, in addition to the above, another pass with a Q-switched alexandrite pigment dye laser at a dose of 6 J/cm<sup>2</sup>. The treated area was evaluated after 6 months. Normal skin was found in three participants in the intervention group and one in the control group. However, the sample size is too small for valid conclusions to be drawn, and there were confounding factors such as the use of different sunblock preparations.

The second RCT [49] was in Taiwan on 33 participants with mixed-type melasma previously unresponsive to hydroquinone. Participants were randomized to receive either 4% hydroquinone cream or four sessions of intense pulsed light and 4% hydroquinone cream over 16 weeks. Intense pulsed light is a broad-spectrum light with wavelengths ranging from 400 to 1200 nm that penetrates the skin's surface and targets specific elements in the skin, such as melanin. There was a co-intervention of a broad-spectrum sunscreen. In the hydroquinone-only group, 64% of the participants were slightly satisfied and 36% were unsatisfied. In the pulsed light and hydroquinone group a higher proportion were slightly satisfied, 76.5%, and 23.5% were unsatisfied. Improvement was also assessed objectively, and a greater reduction in the melanin score was seen in the hydroquinone and intense pulsed light group.

The third RCT [45] was on 20 female patients (skin types II–V) with moderate to severe melasma. Patients were randomly assigned to once-daily triple-combination cream (hydroquinone 5%, tretinoin 0.05%, triamcinolone acetonide 0.1%) for 8 weeks or laser therapy. Laser therapy was four sessions of nonablative 1550 nm fractional (Fraxel Re:store laser, Reliant technologies Inc, Mountain View, CA) laser treatment at 2-week intervals. Patients were instructed to use sunscreen (SPF >50) every 3 h when outside. Participants were assessed objectively with melanin index readings and subjectively with MASI and physician global assessment scores. There was also self-assessment (patient global assessment). At 3-week follow-up there was no significant difference in the MASI or melanin index between the groups. There was also no significant difference from baseline or between the groups on the patient global assessment. There was, however, a significant improvement in both groups on the physician global assessment (*P* < 0.001). Mean treatment satisfaction was significantly higher in the laser group (8.3 vs 5.3; *P* < 0.05). There was recurrence in both groups at 3 months, and at 6 months the follow-up scores on the physician global assessment returned to baseline.

The fourth RCT [35] has been included in the acid peels section. Participants were treated with the pigment-specific Q-1064 nm and one half of the face randomly assigned to be treated with GA peels.

The fifth RCT [50] was a single-blind split-face study on 17 patients (phototypes II–IV) comparing triple-combination cream with TCC and pulse dye laser (PDL – Vbeam; Candela Corporation, Wayland, MA). No demographic data were included. Outcomes were assessed by a single blinded investigator. The MASI score on digital photographs was used. Tolerance and satisfaction were graded by the patients on a VAS. The rationale for using a PDL was to treat vascularization and solar elastosis associated with melasma and possible reduction in recurrence. All patients were recruited in winter, and photographs were taken after treatment and after summer, at least 2 months after the last treatment. There was no difference in response for skin type IV patients for initial improvement and recurrence between the two sides of the face. There was significant improvement in melasma in all treatment groups, but the recurrence of melasma was significantly less in the TCC and PDL-treated side of the face compared with the TCC-only side of the face (*P* < 0.01 vs *P* = 0.13). Half of the patients reported mild irritation with TCC. Three patients with skin type IV developed postinflammatory hyperpigmentation. The authors felt this was due to PDL targeting melanin and suggest not to use this in patients with skin type IV.

The sixth RCT [51], from Korean authors, compared the efficacy and adverse effects of a 1064 nm Q-switched Nd:YAG laser (Spectra VRMIII, Lutronic Corp., Seoul, Korea) when used before or after TCC hydroquinone 4%, tretinoin 0.05%, and fluocinolon acetonide 0.01% (Tri-luma® Galderma Lab LP). The study used “laser toning” treatment with top-hat beam mode, short pulse width, high peak power, and low fluence. Over a period of 16 weeks 13 patients (skin types III, IV) with symmetrical distribution of melasma applied TCC once daily, side effect permitting, on one side of the face for 8 weeks, then were treated weekly for 8 weeks with a Q-switched Nd:YAG laser using a collimation hand piece with a 1064 nm wavelength, a 7 mm spot size, a fluence of 1.6–2.0 J/cm<sup>2</sup> and two passes per session. On the other side of the face the treatment was performed in a reversed order, using laser first than applying TCC. After laser treatment, prednicarbate 0.1% ointment (Dermatop ointment Dermik Laboratories, Bridgewater, NJ) was

used to reduce inflammation. All patients avoided sun exposure and used sunscreen with SPF 50 and UVA protection. Efficacy was assessed weekly using clinical images, MASI scores, spectrophotometry measuring brightness, and overall color differences. Patient self-evaluation was also measured at the end of week 16 and 11 months after treatment. In both groups the overall reduction of the MASI score was significant ( $P < 0.05$ ); however, overall improvement measured by spectrophotometry showed significant improvement only in brightness achieved with TCC followed by laser treatment. In all other groups, spectrophotometry failed to prove significant improvement. Comparing the two methods, laser treatment was more effective than TCC in reduction of MASI ( $P < 0.05$ ), but the overall improvement between the two groups was not significant ( $P > 0.05$ ). Again, spectrophotometry showed no statistically significant improvement between the two methods during or at the end of the treatment period. On patient subjective assessment, laser treatment with pretreatment TCC was significantly more effective than posttreatment TCC.

The seventh RCT [52], from Amsterdam, compared triple treatment therapy (TTT – hydroquinone 5%, tretinoin 0.05%, triamcinolone acetonide 0.1% cream) with nonablative 1550 nm fractional laser therapy (Fraxel Re:store laser, Solta Medical, Inc., Hayward, CA). This was a split-face study involving 29 patients aged 18 or over with skin types 2–4. Patients were followed up for 6 months after the last treatment. Improvement of melasma was assessed by patient's global assessment, patient's satisfaction, physician's global assessment, melanin index, and lightness ( $L$ -value) at 3 weeks, and at 3 and 6 months after the last treatment. This study showed significant worsening of pigmentation on the side treated with lasers ( $P < 0.001$ ). Nine patients (31%) developed postinflammatory hyperpigmentation.

### Drawbacks

In the first RCT [48], two participants in the control group suffered peripheral hyperpigmentation.

In the second RCT [49] there were three drop-outs: two in the control group due to poor compliance and one in the intense light group due to relocation. Side effects in the intense light group consisted of erythema, pain, and microcrust formation. Two patients in this group also suffered transient postinflammatory hyperpigmentation.

In the third RCT [45] the participants in the laser group had erythema (75%), burning (58%), and moderate to severe facial edema (40%). In the triple-combination group, patients reported scaling (55%), erythema (25%), and burning (20%).

In the fifth RCT [50] the authors recognize that the split-face design of the trial was not ideal as hyperpigmentation in melasma is usually asymmetrical. The follow-up period in this study is very short, as melasma can recur sometimes years after treatment. The authors have not provided us with data on individual patients or the length of time between the last treatment and final follow-up.

In the sixth study [51], 23% of patients showed worsening of melasma after TCC treatment; no worsening was reported with laser treatment. Results were maintained with laser in the majority of group A, but it was not achieved in group B. Other side effects reported for TCC were irritation, which resolved after extending intervals between applications (four patients). Only mild pain and erythema were reported after laser treatment.

The seventh study [52] shows significant side effects with nonablative 1550 nm fractional laser therapy and worsening of pigmentation.

### Comment

The first RCT [48] is of particular interest, as it is one of the only trials on dermal melasma that is probably more recalcitrant. The small sample size, however, does not allow firm conclusions to be drawn. Properly designed RCTs are needed to determine the effect of laser therapies in dermal melasma.

In the second RCT [49], the frequency of hydroquinone application in either group is unclear. The rationale for hydroquinone in the control arm where participants have been shown to be unresponsive is also unclear. Additionally, the difference between the two groups, although statistically significant after 16 weeks ( $P < 0.05$ ), was not significant at 36 weeks, indicating a requirement for further treatment courses.

In the third RCT [45], no significant difference was found between laser and TCC by the patients and on the measures of MASI and melanin index. The sample size had been powered to detect a difference in the physician global assessment and may have been too small to detect differences in other outcomes.

The fifth RCT [50] does show some response to treatment with PDL, which is a treatment of vascular lesions. The authors hypothesize that this is due to a possible role of vascularization in the development of melasma.

The findings of the sixth study [51] were limited by small patient number. Long-term outcome measures were only assessed by patient self-evaluation, and no statistical analysis was performed.

In the seventh study [52] the authors argue that the reason for the observed hyperpigmentation was the higher setting used 15 mJ/microbeam.

### Key messages

We found insufficient evidence to evaluate the effect of laser therapies in the treatment of melasma. The second study shows some short-term results with the use of an intense pulse light. Repigmentation 8 weeks after the last course of intense light treatment was noted despite continuous use of hydroquinone and broad-spectrum sunscreen. In one RCT, nonfractional ablative laser therapy (1550 nm) was not found to be significantly different to TCC. In both groups, melasma recurred to baseline at 6-month follow-up. Nonfractional laser therapy may have a short-term benefit. The fifth study shows PDL may help in reducing recurrences of melasma, although the follow-up period was very short in this study. In the sixth study, no significant difference was found when comparing the combination treatment with Nd:YAG laser before or after TCC application. The seventh RCT shows significant problems with the use of nonablative 1550 nm fractional laser therapy and the authors concluded against its use in the treatment of melasma using 15 mJ/microbeam. This study was conducted in springtime, which may explain the higher rate of postinflammatory hyperpigmentation.

### Implications for clinical practice/categorization

Unknown effectiveness.

### Oral and topical vitamins

#### Efficacy

We found one systematic review [21] and three RCTs. The first RCT [27], from Japan, included 176 women and two men over a period of 3 months. Melasma was present in 136 of the patients (76%) and pigmented contact dermatitis in 42 (24%). Specific results for melasma were available from the study report. The RCT compared

oral vitamin E (50 patients), vitamin C (45 patients), and a combination of vitamins E and C (41 patients). After 12 weeks, the physician-rated color difference and photographic findings were used to assess changes. Using color photographs, an improvement was noticed in 69% of those receiving a combination therapy of vitamins E and C, 60% of those receiving vitamin E, and 50% of those receiving vitamin C. These differences did not reach statistical significance. In the objective clinical improvement evaluation, 72% of the participants in the combined-therapy group showed improvement, in comparison with 63% in the vitamin E group and 44% in the vitamin C group. The difference between the combined-therapy and vitamin C groups reached statistical significance ( $P < 0.05$ ).

The second study [53] was a split-face double-blind RCT conducted in Seoul, South Korea, on 29 women (aged 24–49) with melasma. It compared iontophoresis with a topical compound containing ascorbic acid, magnesium-L-ascorbyl-2-phosphate, against distilled-water iontophoresis. This was a split-face trial (with the left- and right-side agents selected randomly), and the patients were treated twice weekly for 12 weeks, with concomitant use of a sunscreen twice a day on both sides of the face. Interestingly, subjective assessment by patients did not show any differences between the two sides, but measurement of the *L* value (measured by a colorimeter) showed a significant difference in favor of ascorbic acid: from  $L = 4.60$  to  $2.78$  ( $P = 0.002$ ), in comparison with control side from  $4.45$  to  $3.87$  ( $P = 0.142$ ).

The third RCT [54], a randomized, double-blind placebo-controlled study, evaluated the effect of oral procyanidin+vitamins A, C, and E among 60 Filipino patients with epidermal melasma. Procyanidin is the main active constituent of French maritime pine (*Pinus pinaster*) with anti-inflammatory and antioxidant properties. Sixty subjects (skin types III–IV) with epidermal melasma were randomized to take either test drug (24 mg procyanidin, 6 mg  $\beta$ -carotene, 60 mg ascorbic acid, 15 IU D- $\alpha$ -tocopherol acetate) or placebo (containing starch) b.d. for 8 weeks. An SPF 24 sunscreen was applied daily. The degree of pigmentation was measured with a mexameter and the MASI score was obtained at baseline and at weeks 4 and 8. By mexametry, average melanin index decreased significantly in the treated group ( $P < 0.0001$ ), while no significant changes were measured in the placebo group. The MASI score improved significantly for both with a between-groups change of  $P < 0.0001$ . Subjective measures like physicians' global assessment score showed moderate to obvious results, but the patients' global assessment score showed a wide range from slight to moderate improvement.

### Drawbacks

There were 10 withdrawals in the Japanese RCT [27]. One participant withdrew because of side effects, while 51 failed to complete the 12-week follow-up. Five people in the group receiving vitamins E and C suffered side effects: two had acne, one had xerosis, one had a mild stomach upset, and one developed metrorrhagia. Eight people in the vitamin E group complained of side effects: four had acne, one had a stomach upset, one had excessive perspiration, and two developed menstrual abnormalities. Side effects were also reported by participants receiving vitamin C: four suffered acne, two hot flushes, one had a stomach upset, and one developed seborrheic dermatitis.

The second RCT [53] reported a mild sense of electric shock in 21% patients, itching and erythema in 7%, and burning sensation and dryness in 3%.

In the third study [54] there were three patients who failed to appear on follow-up and one subject dropped out due to developing a metallic taste. No other side effect was reported.

### Comments

The Japanese study did not have a placebo group, and all of the groups improved. Improvement was better in patients receiving preparations containing vitamin E. A placebo-controlled study is needed to determine the effect of these compounds. Thirty-one people suffered side effects, although it is not clear whether this refers to people with chloasma or whether it included people with other pigmentary disorders. In the second RCT, although the objective evaluation using the colorimeter found a significant difference with more improvement on the vitamin-C-treated side, the participants' self-assessment detected no difference between treatments. The third study reported no standard deviation (SD) values of mexametry, and the MASI score and patient's own assessment showed a wide range of outcomes. It was a study with small patient numbers and lacked long-term follow-up data.

### Key messages

We found limited evidence that a combination of vitamins C and E is better than vitamin C alone. We found no evidence in favor of vitamin C iontophoresis versus placebo. Procyanidin in combination with vitamins A, E, and D might be effective in the short term, but further studies are needed in the future to confirm benefits.

### Implications for clinical practice/categorization

Unknown effectiveness.

### Less conventional therapies

#### Efficacy

We found one systematic review [21], which concluded some efficacy of unconventional therapies. We found six RCTs. The first RCT [55] was in Brazil. It was a double-blind, RCT comparing 4% hydroquinone and a skin-whitening complex developed in France. The cream contained: (1) extract of uva ursi, which provokes chemical discoloration of melanin and competes with the tyrosinase enzyme; (2) biofermented *Aspergillus*, which chelates copper ions, which are essential for tyrosinase enzyme activity; (3) grapefruit extract, rich in citric and malic acids, with an exfoliative action; (4) rice extract, rich in oligosaccharides, with a hydrating function. The study was conducted in 30 women aged 38–56, with Fitzpatrick skin types III–V, and with no previous treatments over a period of at least 6 months. The patients were randomly assigned to receive either 4% hydroquinone or skin-whitening complex on one side and a placebo cream on the other side. The treatment was carried out for 3 months, with the addition of a sunblock during the treatment period. Photographs were taken before and after treatment and clinical evaluation was performed by two independent observers and by the patients themselves. The two groups were evaluated separately. Group 1 (hydroquinone vs placebo) had an improvement of 76.9% and group 2 (skin-whitening complex vs placebo) showed an improvement of 66.7%; however, the difference was not statistically significant on Fisher's test ( $P = 0.673$ ).

The second RCT [56] was a split-face trial on 28 women with mixed melasma in the Philippines. Participants applied Gigawhite solution or placebo to either the right or left side of the face twice daily for 12 weeks. Gigawhite is a complex of botanical origin containing mallow, peppermint leaf, *Primula veris*, *Alchemilla vulgaris*,

*Melissa officinalis* leaf extract, and *Achillea millefolium* extract. There was also a co-intervention of SPF 60 sunscreen. Three participants had a greater than 90% improvement, 15 had a greater than 50% improvement, and seven participants a greater than 25% improvement. It is unclear if this was compared with baseline or if compared with the placebo side. The decrease in MASI was not significantly different for the two sides, although there was greater decrease on the Gigawhite-treated side. There was a decrease in MASI by 18.5% (mean) on the Gigawhite side compared with 13.5% (mean) on the placebo side. Although no significant differences were noted on subjective measures, the colorimeter analysis found a significant difference with improvement of 6.9% (mean) in luminance on the Gigawhite side compared with 1.03% (mean) on the placebo side at 12 weeks (the trial authors stated  $P = 0.013$ ).

The third RCT [57] was a split-face trial on 32 women with moderate to severe melasma. Participants were randomized to rucinol (4-*n*-butylresorcinol) serum or placebo to the right or left side of the face applied twice daily for 12 weeks. Rucinol is a resorcinol derivative shown to inhibit the activity of both tyrosinase and TRP-1. All participants were provided with an SPF 60 broad-spectrum sunscreen. There was also an optional stage of the study (phase 2) where open treatment of the whole face was carried out using the active product for 3 months during which time participants received rucinol on both sides of the face. A clinical pigmentation score from 0 (no pigmentation) to 10 (brown pigmentation of high intensity) was allocated for different regions of the face (forehead, malar, and chin) and a mean taken. A significantly lower pigmentation score was achieved on the side treated with rucinol ( $P = 0.027$  reported). The mean clinical pigmentation score at baseline in the rucinol group was 7.5 (SD 1.9) and at 12 weeks it was 6.2 (SD 2.3). In the placebo group the score at baseline was 7.5 (SD 1.9) and at 12 weeks was 6.7 (SD 2.1). The small reduction in score seen in the placebo group was attributed to sunscreen use. Colorimetric assessments using the chromameter confirmed that the rucinol-treated side was significantly lighter and less yellow at 12 weeks. When pigmentation scores in phase 2 (at 16, 20 and 24 weeks) were compared with those recorded at the end of 12 weeks, the differences were found to be highly statistically significant ( $P = 0.004$  at 16 weeks) at each visit for the side previously treated with vehicle. For the side treated with rucinol throughout the study, there was also a statistically significant improvement at 16 weeks compared with 12 weeks. The authors concluded that the effect of rucinol was maintained until the end of the study at 24 weeks.

The fourth RCT [58] was conducted in Belgium on 27 women with melasma affecting the forehead for at least 6 months. Participants were randomized to Thiospot intensive, a cosmetic whitening formulation containing ethyl linoleate, thioctic acid, octadecanedioic acid, lactic acid, and ethyl-hexyl-methoxycinnamate, or Eucerin non-whitening skin care, both applied twice daily for 3 months. Thiospot is purported to inhibit the enzyme tyrosinase involved in melanin synthesis. There was a significant difference between the groups. At 3 months the group receiving Thiospot had lighter skin with a lower melanin index measured using a mexameter ( $P < 0.01$ ). The significant improvement in melasma in the Thiospot group was also confirmed on the other objective measurements of video-recorded ultraviolet light reflection, corneometer, as well as the physician's subjective assessment.

The fifth RCT [59] from San Jose, CA, a split-face, randomized, double-blind, placebo-controlled pilot study evaluated the efficacy of a proprietary synthetic oligopeptide (Lumixyl™, Emed, Inc., Westlake Village, CA) with competitive tyrosinase-inhibiting prop-

erties on patients with moderate recalcitrant, epidermal melasma (Wood's light assessment). Five female patients (skin type IV) with Hispanic or Asian descent who just failed a 6-month twice daily treatment with Tri-Luma® were enrolled and treated with 0.01% Lumixyl and vehicle alone on either side of the face, twice daily over a period of 16 weeks. The investigators rated improvement of melasma on a 10-point scale by using digital photographs at weeks 12 and 16. Additionally, at week 16, physicians and patients graded overall facial appearance using a four-point global assessment scale and patients' satisfaction with the treatment were also evaluated. Both patients' and physicians' assessments showed >40% improvement in melasma at week 12 and >50% at 16 weeks on the oligopeptide-treated site versus 4% improvement on the placebo site. Global assessment also demonstrated >70% improvement in overall appearance of the facial skin on the site treated with the active ingredient versus 15% improvement on the placebo-treated site. Patients were either very satisfied or extremely satisfied on the oligopeptide-treated site compared with mild satisfaction and not satisfied at all on the placebo site.

The sixth RCT [60], from Brazil, compared a combination of plant extract belides, emblica, and licorice 7% (group A) with hydroquinone 2% (group B) in the treatment of melasma. This study involved 56 females, 18–60 years of age, phototypes I–IV, with epidermal or mixed melasma. Before entering the study they had to use an SPF 50 sun block for 60 days. They were randomized into two groups; six patients did not complete the study. Evaluations were done 15 days apart for 60 days by the patients, physicians, and with digital photography (VisiaR, Canfield Imaging System – Fairfield, EUA). Both groups showed significant improvement in lightening of melasma by physician-reported evaluation (group A: 78.3%; group B: 88.9%) and patients' self-evaluation (group A: 91.3%; group B: 92.6%); these results were statistically significant ( $P < 0.001$ ), with no differences between groups ( $P > 0.05$ ). Digital photography results also showed similar results.

### Drawbacks

In the first study [55], there were no side effects in the extract of uva ursi skin-whitening group, in comparison with the 4% hydroquinone group, in which 25% patients suffered minor side effects.

In the second RCT [56] there were no adverse effects due to Gigawhite or placebo.

In the third RCT [57] there were four withdrawals (12.5%), and 28 participants completed the 12-week study. No reasons for withdrawal were given. There were 12 adverse events reported, the majority of which were mild. The authors felt only one was related to the study product, a small depigmented spot due to placebo. It is unclear if the numbers of adverse events include the extended phase of the study.

In the fourth RCT [58], no adverse events were mentioned in the text.

In the fifth study [59], the oligopeptide was well tolerated with no side effects.

In the sixth RCT [60], two patients in group A and seven in group B suffered mild side effects. There were six withdrawals, which were due to noncompliance with the study protocol.

### Comments

The first RCT [55] did not show any significant improvement in melasma with the use of the skin-whitening complex compared with hydroquinone 4%.

In the trial [56] of a botanical extract, Gigawhite 5%, no significant difference to placebo was noted on subjective assessment by the physicians, though colorimeter analysis showed that the side treated with Gigawhite was significantly lighter. The participants' self-assessment was also poorly reported. It is unclear if the percentage improvement recorded was compared with baseline or if compared with the placebo side. In addition, it was stated that two participants had no improvement and one had worsening of melasma; these three appear to have been unaccounted for in the patient self-assessment above.

In the third RCT [57], although a reduction in the clinical pigmentation score was also seen at the earlier assessment of 8 weeks, the score was not significantly different from baseline, and rucinol may have a slower onset of action.

The fourth RCT [58] had unusual inclusion criteria of forehead melasma. It is unclear if participants were excluded if they had melasma elsewhere (e.g., cheeks or chin). No explanation is given as to why the authors limited inclusion to forehead melasma. There was no description of the type of melasma and no baseline characteristics for each group provided.

There were only five patients enrolled in the fifth study [59]. No objective assessment was carried out and no long-term follow-up was arranged.

In the sixth RCT [60], methods of randomization were not discussed. The evaluators were not blinded in this study.

### **Key messages**

Each agent was trialed in one RCT, each providing limited evidence. We found no evidence in favor of skin-whitening complex extract of uva ursi versus hydroquinone 4%. Although on colorimeter analysis there was significantly more improvement in melasma on the Gigawhite-treated side, the clinical improvement may have only been minimal as the physicians in the study did not note a significant difference to placebo. Rucinol may be effective, though it may have a slower onset of action. Thiospot was more effective than placebo at lightening melasma, though this was in a small study with some flaws. The oligopeptide Lumixyl, a competitive inhibitor of tyrosinase, might be a candidate for further clinical evaluation, but at the moment there is no evidence to support its effectiveness in the treatment of melasma. The sixth RCT shows similar efficacy of plant extracts belides, emblica and licorice 7% compared with 2% hydroquinone. These should be further evaluated by a larger double-blinded study.

### **Implications for clinical practice/categorization**

Unknown effectiveness.

## **How effective are therapeutic interventions in men?**

### **Case scenario 55.4**

A 40-year-old Latin-American man living in California has had melasma for 3 months. It appeared after a beach holiday. He is not on any regular medication, but has a family history of melasma.

### **Efficacy**

We identified no studies assessing the effects of therapeutic interventions exclusively in men. Although several RCTs included a few men, none of them carried out a subgroup analysis, and none would have had sufficient power to identify any clinically relevant differences.

### **Comment**

On the basis of expert opinion, the same treatments used in non-pregnant women may be considered appropriate in men with melasma.

### **Key messages**

We found no evidence specifically evaluating the effects of treatment in men.

### **Implications for clinical practice/categorization**

Unknown effectiveness.

## **Implications of the available evidence**

### **For consumers (the public)**

Current opinion, based on known risk factors, suggests that measures preventing exposure to sunlight may reduce the risk of the development and recurrence of melasma. From the available trial evidence, therapies likely to be beneficial are AZA, hydroquinone, and TCC (fluocinolone acetonide 0.01%, hydroquinone 4%, tretinoin 0.05%).

### **For clinical practice (health-care providers)**

From the available evidence, a treatment likely to benefit patients with melasma is 2–4% hydroquinone with sunscreens, and TCC. The use of hydroquinone for melasma has been limited recently, following several case reports of it causing exogenous ochronosis. However, there were no reports of this side effect in any studies with follow-up periods of up to 24 months. TCC (fluocinolone acetonide 0.01%, hydroquinone 4%, tretinoin 0.05%) was more effective than any of the agents in dual combination and also was found to be more effective than 4% hydroquinone alone. A recent comprehensive review by Sheth and Pandya [61] also suggests a combination of a retinoid, hydroquinone, and a topical steroid to be used as a first-line treatment for melasma.

We did not find convincing evidence for the effectiveness of AZA, topical retinoids, topical corticosteroids, GA, oral vitamins E or C, lasers, or combined therapies.

### **For research (research agencies and researchers)**

We found inconclusive evidence of the effectiveness of topical AZA, steroids, topical retinoids, GA, vitamin C, and laser therapy. These are commonly used therapies for melasma in clinical practice and would require further RCTs to validate their use. Lasers offer a potential advantage over conventional therapies, as the time to clearance can be much reduced. We found only a few studies that looked at patient-based outcomes. Most studies excluded patients with mixed or dermal-type melasma or patients with known risk factors (e.g., recent delivery, oral contraceptive or hormone replacement therapies). Future studies should specify more clearly what type of melasma is being studied, and if participants with a variety of epidermal and dermal patterns are included, then an appropriate subgroup analysis or interaction test should be performed to test the hypothesis that dermal patterns are less responsive to therapy. Future studies need to be much larger, prospectively registered, and reported properly following the latest revision of CONSORT [62].

## Key points

- No clear evidence supports preventive interventions in high-risk populations. Current opinion, on the basis of the known risk factors, suggests that preventing exposure to sources of ultraviolet light, such as sunlight, may reduce the risk of developing melasma.
- No clear evidence supports any therapeutic intervention in pregnant or breastfeeding women. Current opinion suggests that such women with melasma may benefit from using broad-spectrum sunscreens and avoiding exposure to ultraviolet light, such as sunlight.
- Limited evidence from a single RCT evaluating the effect of therapeutic sunscreens shows that, during the 3-month study period, the majority of women using hydroquinone had improvement, regardless of the addition of sunscreen to their treatment. The study did not describe whether women used other strategies to avoid sunlight.
- Evidence is insufficient to support the use of topical steroids in melasma. There is controversy over the use of topical steroids in this condition. There is limited evidence from one RCT of a quicker response when topical steroids are used sequentially with AZA.
- An effect of topical retinoids on melasma has not been shown, but the available studies found that side effects were common.
- In a small trial, AZA was found to be superior to 2% hydroquinone in achieving improvement in people with melasma. We found no solid evidence comparing AZA with placebo. AZA was associated with a higher incidence of side effects.
- Limited evidence from one RCT suggests that hydroquinone plus sunscreen was better than sunscreen and placebo.
- The evidence is insufficient to assess the effects of GA.
- TCC (fluocinolone acetonide 0.01%, hydroquinone 4%, tretinoin 0.05%) was more effective than any of the agents in dual combination and also was found to be more effective than 4% hydroquinone alone. Overall, we found no good evidence of the effects of other combined therapies in comparison with a placebo or other preparations. The studies had methodological flaws, including small sample sizes, which compromised the validity of results.
- We found insufficient evidence to evaluate the effect of laser therapies in the treatment of melasma. One nonrandomized study showed faster improvement with intense pulsed-light therapy. Postinflammatory hyperpigmentation can be a significant side effect of both PDL and Nd:YAG lasers, especially in patients with skin type IV or above.
- We found insufficient evidence that a combination of oral vitamins C and E is better than oral vitamin C alone. We found no evidence of the effects of these therapies in comparison with placebo.
- We found insufficient evidence for the efficacy of a skin-whitening cream containing extract of uva ursi, biofermented *Aspergillus*, grapefruit extract, oligopeptide Lumixyl, and rice extract in comparison with hydroquinone 4%. In a single-blinded study, plant extracts besides, emblica and licorice 7% showed similar efficacy to 2% hydroquinone. This needs further evaluation with larger double-blinded studies.
- No studies have assessed the effect of treatments specifically in men.

## SECTION 5 Common ailments with significant cosmetic impact

Berthold Rzany, editor

### CHAPTER 56

## Male and female androgenetic alopecia

Hans Wolff and Kathrin Giehl

Department of Dermatology and Allergology, Ludwig-Maximilians-University, Munich, Germany

### Background

#### Definition

The term “androgenetic alopecia” (AGA) describes a genetically determined condition leading to permanent loss of hair in men and women with normal levels of androgens. Synonymous terms are male-pattern and female-pattern hair loss. Most men with AGA show a typical pattern of hair loss, often beginning at the temples and in the vertex area [1–3]. In contrast, most women with AGA have a diffuse thinning in the midline of the scalp [4]. In many, but not all, men and women, the hair loss is accompanied by increased shedding of telogen hair, which is a reflection of shortened anagen growth phases [5,6].

#### Prevalence

AGA affects approximately 30% of men under 30 years of age, 50% under 50 years of age, and 70% under 70 years of age [1,7]. In women, the incidence before menopause is 5–10%, rising to 20–30% after the menopause [8].

#### Etiology

Microscopically, AGA is characterized by progressive shrinking of scalp hair follicles [9]. In many patients, AGA is accompanied by an acceleration of the hair growth cycle, as reflected by decrease of anagen and increase of telogen hair in the trichogram [9]. However, some patients have a normal anagen/telogen ratio despite slowly progressive AGA. Whether and when a scalp hair follicle miniaturizes is dependent on two factors: genetics and androgens [10,11]. Several genes responsible for shrinkage of a scalp hair follicle are suspected [11–14], but are not yet all known. Each scalp hair follicle carries individual genetic information that determines whether and when it will develop a sensitivity towards androgens. Once a scalp hair follicle has become sensitive to androgens, it will progressively shrink during the following years. In men, the most important androgen-driving AGA is dihydrotestosterone (DHT). Within the cells of the hair follicle, DHT is derived from its precursor testo-

sterone by two enzymes: the 5- $\alpha$ -reductase types I and II [15]. DHT appears to be less important in women than in men [16]. In general, androgens can be considered potentially harmful and estrogens potentially beneficial for scalp hair growth in women [14].

#### Prognosis

Without treatment, AGA progresses until all hair follicles that have developed a genetically determined sensitivity towards androgens are miniaturized [9]. The extent of AGA depends on the number of hair follicles with genetic sensitivity to androgens. In its maximal expression, all hairs can be lost from the top of the scalp. In both men and women, occipital hair follicles never develop sensitivity to androgens; they are never lost in AGA.

#### Aims of treatment

Treatment of AGA has two major goals. First, it is important to reliably stop further hair loss. The term “hair loss” does not describe telogen effluvium, but refers to permanent visible thinning of scalp hair density due to miniaturization of hair follicles. Second, some men and women benefit so strongly from treatment that they can regrow hair to a certain extent – their hair density can be increased by reenlargement of individual hair follicles.

#### Relevant outcomes

- *Stopping further hair loss:* in a clinical study setting, this has to be documented after intervals of at least 1 year by microscopic methods such as hair counts or increase of hair weight in a representative area of hair loss.
- *Increase of visible hair density:* this has to be documented by standardized scalp hair photography [17].

A change in the anagen/telogen ratio does not reliably assess the efficacy of treatment against further progression of AGA, because not all men and women with AGA have abnormal anagen/telogen ratios. In addition, some patients with long-standing telogen effluvium never develop AGA [18]. The trichogram, therefore, cannot reliably measure the efficacy of treatment against AGA.

## Methods of literature search

In the PubMed database, different search terms were used for male and female androgenetic alopecia. For male androgenetic alopecia, the search terms were: “((androgenetic and alopecia) or (\*male and pattern and baldness)) and (finasteride or minoxidil).” For female androgenetic alopecia, the search terms were “((female and androgenetic and alopecia) or (female and pattern and baldness)) and (minoxidil or antiandrogen\* or cyproterone acetate or (cyproterone and acetate) or cyproterone acetate or estrogen\* or estradiol).”

## Questions

### Which topical or systemic treatment can stop further hair loss and increase hair density in men?

#### Case scenario 56.1

The patient is a 28-year-old computer specialist with a 3-year history of gradual hair loss starting at the temples and now also involving the top of the scalp (Figure 56.1).

#### Topical minoxidil for men with androgenetic alopecia

##### Efficacy

We found no systematic reviews. Several randomized controlled trials (RCTs) show that minoxidil 2% or 5% solution applied twice daily can increase test-area hair counts and hair weights in men with AGA [19,20].

##### Drawbacks

In approximately 5% of men, minoxidil causes redness and itching of the scalp skin. In most men, this effect appears to be nonspecific irritation by polyethylene glycol or other solvents; in some, however, a specific type IV allergy against minoxidil is possible [21]. Patients sometimes attribute specific systemic effects such as hypotension or an increase in heart rate to minoxidil, but this is implausible, because serum concentrations of minoxidil are very low after twice-daily topical administration. A large 1-year prospective study including more than 10 000 male minoxidil users showed that there are no serious systemic side effects [22].

##### Comment

Minoxidil 5% solution applied twice daily is a safe and effective topical treatment for AGA in men. There are no conclusive data on

how often minoxidil solution can reliably stop hair loss and increase visible regrowth of hair in men. One of the possible mechanisms is improvement of the microcirculation in the dermal papilla [23–25].

#### Implications for clinical practice

Minoxidil 5% solution can stop hair loss in many men, but hair loss resumes when the applications are stopped. There are no systemic side effects.

#### Systemic finasteride for men with androgenetic alopecia

##### Efficacy

We found no systematic reviews. Two-year results from the largest RCT were reported by Kaufman *et al.* [26]. This international multicenter clinical trial of more than 1500 patients demonstrated a significant increase in hair counts in the finasteride treatment group after 1 year. In the second year, there was stabilization of the increased hair count in the finasteride group. Men on placebo had a progressive loss of hair count in the vertex test area. Men who were switched from finasteride to placebo after 1 year lost the hair gained under finasteride. Therefore, as with other medical treatments for AGA, finasteride needs to be taken permanently to show therapeutic benefit. Visible hair density was also documented by a standardized camera device [17]. After 1 and 2 years, the before and after pictures were judged by an expert panel of dermatologists, who were blinded to the treatment modality. After 1 year, 48% of men in the finasteride treatment group had visibly increased hair density in the vertex area, compared with 7% in the placebo group. After 2 years of treatment, 66% of the men in the finasteride group had visibly increased hair density, compared with only 7% in the placebo group [26]. On the basis of the 5-year data [27], hair loss can be stopped in 90% of men taking finasteride, compared with 25% in the placebo group. In addition to stoppage of hair loss, an increase in hair density was seen in 48% of the men in the finasteride group, compared with 6% of men in the placebo group after 5 years of the study.

Other RCTs have demonstrated that finasteride significantly improves the anagen/telogen ratio [28], increases individual hair weight [29], also has positive effects on the frontal hair line [30], is as effective as minoxidil [31], and also works well in men between 40 and 60 years of age [32].

##### Drawbacks

There were no side effects on the liver, kidney, or any other internal organ [26]. Serum hormones were unaffected, with the exception of a desired 70% decline in DHT and a compensatory 10% increase in testosterone. The following sexual side effects were reported for the finasteride and placebo groups, respectively: a decrease in libido of 1.9% versus 1.3%; a decrease in potency of 1.4% versus 0.9%; and a decrease in ejaculate volume of 1.0% versus 0.4%. Although the differences between the finasteride and placebo groups were small and statistically not significant [26], and were not seen in other studies [33], finasteride must be considered capable of causing such effects in some men. A separate study found sperm function parameters to be unaltered by finasteride 1 mg [34].

##### Comment

Finasteride 1 mg is a safe and effective drug for the treatment of AGA in men. Finasteride inhibits the enzyme 5 $\alpha$ -reductase type II, thereby preventing the intracellular conversion of testosterone into its more active metabolite DHT [35]. In men, DHT is essential for

Figure 56.1 Typical male-pattern hair loss in a 28-year-old patient.

the development of AGA, and finasteride decreases DHT by 70%, both in the scalp skin and in serum [36].

### Implications for practice

In 90% of men treated, finasteride 1 mg can stop hair loss (for at least 5 years) while it is being taken. Systemic side effects such as reduction of libido and erectile function are infrequent (1–2%) and often transient.

## Which topical or systemic treatment can stop further hair loss and increase hair density in women?

### Case scenario 56.2

The patient is a 35-year-old teacher with a 5-year history of gradual hair loss starting at the midline of her scalp (Figure 56.2). Her mother also had thin hair; her father was bald.

### Topical minoxidil for women with androgenetic alopecia

#### Efficacy

We found one systematic Cochrane Collaboration review [37]. Several RCTs demonstrate that minoxidil 2% solution applied twice daily can increase test-area hair counts and hair weights in women with AGA [38,39]. Most trials were conducted for at least 1 year. When effective, minoxidil solution increased visible hair density within 6 months. After 6 months, no further increase was to be expected. A large American multicenter study included 308 women with AGA; 256 women completed the trial. In the minoxidil group, the increase of nonvellus hairs was significantly larger than in the placebo group. On the investigators' assessment, more minoxidil-treated women had visible regrowth of hair than in the placebo group [40].

#### Drawbacks

Patients sometimes attribute specific systemic effects such as hypotension or an increase in heart rate to minoxidil, but the very low serum concentrations of minoxidil after twice-daily topical admin-

Figure 56.2 Typical female pattern hair loss in a 35-year-old patient.

istration make this implausible. In addition, a large prospective study showed that there are no serious systemic hypotensive side effects in female minoxidil users [22]. Minoxidil causes redness and itching of the scalp skin in approximately 5% of women. In most women, this effect appears to be nonspecific irritation by polyethylene glycol or other solvents; in some, however, a specific type IV allergy against minoxidil is possible [21]. In women with oriental, dark complexion, hypertrichosis in the face and other parts of the body can occur as a side effect of minoxidil [41]. Hypertrichosis usually subsides after the drug has been stopped. A study by Lucky *et al.* showed similar efficacy rates of 5% and 2% minoxidil solution for female androgenetic alopecia [38]. However, there was an increased occurrence of pruritus, local irritation, and hypertrichosis in the 5% topical minoxidil group. The manufacturer, therefore, prefers the use of 2% minoxidil solution in women.

#### Comment

Minoxidil 2% solution applied twice daily is a safe and effective topical treatment for AGA in some women while it is used. Minoxidil solution can reliably stop hair loss and increase obviously visible regrowth of hair in 10–20% of women.

### Implications for clinical practice

Currently, minoxidil 2% solution is the only effective way of treating AGA in women. There are no systemic side effects.

## Systemic estrogens and/or antiandrogens for women with androgenetic alopecia

#### Efficacy

Because estrogens have many antiandrogenic actions, it is thought that they may have a positive influence on hair growth. Antiandrogens such as cyproterone acetate and chlormadinone acetate directly block the androgen receptor. However, most women with AGA have normal estrogen and androgen levels [42]. Positive effects of estrogens and/or antiandrogens on hair growth are therefore questionable. There are no systematic reviews. One RCT compared the efficacies of the antiandrogen cyproterone acetate, 52 mg daily on days 1–20 of the cycle, with a twice-daily 2% minoxidil application in 66 women with AGA grades Ludwig I (67%), II (31%), and III (2%). The study duration was 1 year, and each treatment group consisted of 33 women. The main outcome was number of strong hairs ( $>40\mu\text{m}$  in diameter) in a test area as detected by the phototrichogram. After 1 year, hair counts in the  $0.32\text{cm}^2$  test area were  $-2.4 \pm 6.2$  in the cyproterone acetate group and  $+6.5 \pm 9.0$  hairs in the minoxidil group [43]. Thus, 2% minoxidil was significantly more effective than cyproterone acetate.

#### Drawbacks

Systemic 17- $\beta$ -estrogens are thought to slightly increase the risk of breast cancer and (particularly in women with coagulation disorders) deep venous thrombosis.

#### Comment

In theory, women using estrogens and/or antiandrogens may benefit from treatment [44]. However, as yet, there is little convincing evidence that estrogens and/or antiandrogens can stop or delay AGA.

### Implications for practice

There are no convincing data showing that systemic estrogens or antiandrogens are effective in women with AGA. We are therefore

reluctant to treat women with AGA with systemic hormones that increase the risk of deep venous thrombosis and fatal embolism.

## Key points

### Men with androgenetic alopecia

- Topical minoxidil 2% or 5% solution applied twice daily to the scalp is effective for many men with AGA, but hair loss resumes when the applications cease. The RCTs reported are too small to establish percentages for successful stoppage of hair loss and frequency of visible regrowth of hair.
- Large RCTs show that systemic therapy with finasteride 1 mg per day can stop further hair loss in 90% and increase visible hair density in 48% of treated men. However, hair loss resumes when treatment is stopped.

### Women with androgenetic alopecia

- Topical minoxidil 2% solution applied twice daily to the scalp is moderately effective for some women with AGA.
- One RCT using modern methods of hair growth evaluation showed that the systemic antiandrogen cyproterone acetate is less effective than 2% minoxidil solution.

# Alopecia areata

**Rod Sinclair**

Professor of Medicine, University of Melbourne; Director of Dermatology, Epworth Hospital Melbourne, Australia

## Background

### Definition

Alopecia areata is a familial inflammatory disease with an unknown environmental trigger. It is characterized by discrete, well-demarcated, circular areas of nonscarring terminal hair alopecia and its clinical presentation is most often multifocal [1]. Bald areas frequently contain pathognomonic exclamation-mark hairs. It may occur on any hair-bearing area of the body. Severe disease is disfiguring and may produce total loss of scalp hair (alopecia totalis) or universal loss of body hair (alopecia universalis). There may be associated nail changes; however, the skin is normal.

### Incidence/prevalence

The true incidence and prevalence of alopecia areata is unknown. It is estimated that 1.7% of the population will experience an episode of alopecia areata during their lifetime [2]. Alopecia areata accounts for 2% of new dermatological outpatient department attendances in the UK and USA [3]. While alopecia areata can develop at any age, 30–40% of cases appear before 21 years of age and 20–30% after 40 years of age [4]. The condition occurs with equal incidence in both sexes. The percentage of patients with alopecia areata who go on to develop alopecia totalis/universalis is not known, but estimates range from 7 to 30% [5].

### Etiology

Alopecia areata is thought to be an organ-specific autoimmune disease with a complex genetic etiology with polygenic susceptibility and severity loci interacting with environmental factors [6]. The rate of concordance among monozygotic twins is about 55%, and approximately 20% of patients overall have a positive family history [5]. A large number of potential environmental triggers have been evaluated, including emotional stress, pregnancy, and intercurrent infections. However, no definite associations have been identified [7].

### Prognosis

Regrowth from an initial patch occurs within 6 months in 33% of cases, and within 1 year in 50%; however, 33% never recover from the initial episode [8]. Almost every patient will develop further patches if followed for long enough [4].

Adverse prognostic factors include age less than 10 years at time of first episode, ophiasis pattern or total alopecia, poor response to previous treatment, and the presence of associated atopy, nail dystrophy, or Down's syndrome [1]. The duration of alopecia areata prior to treatment is also thought to be an independent prognostic factor [9].

### Diagnostic tests

The diagnosis of alopecia areata is a clinical one. Exclamation-mark hairs in circular bald areas are pathognomonic. Rarely, a biopsy is required to exclude other forms of hair loss. The hallmarks of an active lesion are a dense lymphocytic infiltrate around the anagen hair bulbs and uniform miniaturization of terminal hairs into vellus-like hairs [10]. Telogen hairs are not inflamed, and there are decreased numbers of terminal anagen hairs.

### Aims of treatment

The aim of treatment is to improve the patient's quality of life either by achieving cosmetically acceptable hair regrowth, or by encouraging the patient to live with the hair loss. Unfortunately, the environmental events that trigger episodes of alopecia areata are unknown, and so relapse can be neither predicted nor prevented. Treatment is often unsatisfactory and centers on the provision of emotional support to distressed patients and their families.

### Methods of search

- Clinical evidence search and appraisal (May 2012).
- Supplementary search of Medline from 1966 to 2006.

Figure 57.1 Patchy alopecia areata.

- Other references obtained from reference lists in all identified review articles and relevant sections of new editions of multiple-author textbooks of dermatology and hair diseases.
- Cochrane review on interventions for alopecia areata published in 2008 was studied for new content and references.
- A new literature review was carried out on articles published between 2006 and 2012 for this edition.

## Questions

### What are the effects of treatment for patchy alopecia areata?

#### Case scenario 57.1

Sarah is 22 years old and has two patches of alopecia areata over the frontal and parietal scalp that have been present for 8 months (Figure 57.1). At the age of 10, she developed alopecia totalis, with spontaneous regrowth after 9 months. At the age of 14, she developed a solitary patch of alopecia areata, with regrowth after two intralesional injections of triamcinolone acetonide 6 weeks apart.

She has a history of atopy, her mother has idiopathic hypothyroidism, and a great-aunt became totally bald after receiving a telegram notifying her of her husband's death during the Second World War. Sarah's only recent stress was breaking up with her boyfriend of 4 years; however, that occurred after the hair loss had begun.

#### Intralesional corticosteroids

##### Benefits

I found no systematic reviews. One randomized controlled trial (RCT) and one observational comparison study confirm that intra-dermal injections of triamcinolone acetonide, 5 mg/mL with a needle-less injector, produced rapid regrowth of hair in a high proportion of subjects with limited disease within 4–6 weeks.

##### Versus placebo

In a report of 84 patients using normal saline controls, 86% of patients treated with triamcinolone responded, in comparison with only 7% of control patients [11]. Injections of triamcinolone acetonide, 0.1 mL of 5 mg/mL, were given at weekly or two-weekly intervals on three occasions. The number of injections was determined by the size of the area of alopecia, with each injection producing a

tuft of hair approximately 0.5 cm<sup>2</sup>. Ninety-two percent of patients with localized disease showed regrowth at 6 weeks, in comparison with 61% of those with alopecia totalis. This decreased to 71% at 12 weeks for alopecia areata and 28% for patients with alopecia totalis, without further treatment. Topical tretinoin was used as an adjunctive treatment to intralesional corticosteroids in one study [12].

##### Versus each other

In an observational study comparing triamcinolone acetonide and triamcinolone hexacetonide involving 34 areas of alopecia in 11 patients, 64% of the sites injected with triamcinolone acetonide and 97% of the sites injected with triamcinolone hexacetonide regrew [13].

##### Versus topical corticosteroids

One RCT compared intralesional triamcinolone 10 mg/mL every 3 weeks with topical betamethasone valerate 0.1% foam and tacrolimus ointment 0.1%. One hundred and five patients with localized alopecia areata were enrolled, but data were evaluated on only 78 who completed the trial. On completion of the study at 12 weeks, 15/25 patients in the intralesional triamcinolone group, 15/28 in the betamethasone foam group, and 0/25 in the tacrolimus group had achieved >75% hair regrowth in their target patch [14].

##### Harms

Hemorrhage can occur at the puncture site, but can easily be controlled with pressure [11]. No cases of persistent atrophy of skin were seen. The plasma cortisol level was measured in one patient and showed significant suppression, raising the possibility of a systemic effect [11].

##### Comments/implications for clinical practice

Despite the lack of RCTs, intradermal injection of triamcinolone acetonide in concentrations ranging from 2.5 to 10 mg/mL either with a needle or with a needle-less injector is the most widely used first-line treatment for patch alopecia areata. Rapid hair regrowth is achieved in a high proportion of subjects within 4–6 weeks. Dermal atrophy is common, but usually self-limiting. Topical tretinoin is not widely used as an adjunctive treatment, and the reported beneficial effects have not been independently substantiated.

#### Topical immunotherapy

Three agents have been used for topical immunotherapy: dinitrochlorobenzene, diphencyprone, and squaric acid dibutyl ester (SADBE). All are applied topically at weekly intervals following initial sensitization.

##### Benefits

I found one systematic review of published case series on the use of topical immunotherapy with diphencyprone, which concluded that 50–60% of patients achieve a worthwhile response. Patients with limited disease have higher response rates than patients with alopecia totalis/universalis [15].

##### Versus placebo

I found no RCTs. In the largest series reported to date of diphencyprone in the treatment of alopecia areata, 148 consecutive patients were evaluated for unilateral regrowth following unilateral treatment [16]. At 32 months, cosmetically significant regrowth was obtained in 17.4% of those with alopecia totalis/universalis, in

60.3% of those with 75–99% hair loss, in 88.1% of those with 50–74% hair loss, and in 100% of those with 25–49% hair loss. The only other independent predictor of treatment response was the age of onset of alopecia areata, with an older age of onset portending a better prognosis [17]. Relapse after achievement of cosmetically significant regrowth occurred in 62.6% after a 37-month follow-up period and was not prevented by maintenance therapy [17].

#### ***Versus each other***

A controlled trial compared SADBE, diphencyprone, minoxidil, and placebo in patients with patchy alopecia areata involving less than 40% of the scalp [18]. The study included 119 patients and was continued for at least 6 months. No significant differences were found between the different therapies used and placebo.

#### ***Harms***

Dinitrochlorobenzene is mutagenic on the Ames test [19]. A moderately severe allergic contact dermatitis is necessary for success of the therapy [20], which if severe may necessitate temporary suspension of treatment. Tender regional lymphadenopathy is common, but usually mild and self-limiting. Generalized dermatitis is uncommon, but may necessitate permanent cessation. Contact urticaria, vitiligo, and erythema multiforme have been reported [21]. Dinitrophenol, a metabolite of dinitrochlorobenzene, has been reported to cause hepatic and renal changes, convulsive seizures, and hyperthermia [22].

#### ***Comments/implications for clinical practice***

Diphencyprone is not licensed in the USA. Immunotherapy for alopecia areata is only available in specialist treatment centers. I found no RCTs on the use of topical immunotherapy; however, a number of studies have demonstrated unilateral hair regrowth after unilateral treatment. This protocol conforms to the published investigational guidelines for alopecia areata [15]. In almost all case series, patients with limited disease have higher response rates than patients with alopecia totalis/universalis. In contrast to other studies, Shapiro *et al.* [23] found that a long duration of disease did not necessarily preclude a positive response to treatment with diphencyprone. Tosti *et al.* concluded from their work that transferring nonresponder patients with alopecia totalis or universalis to other therapies is generally useless [24].

#### **Topical corticosteroids**

##### ***Benefits***

I found no systematic reviews. There were two well-conducted RCTs with adequate patient numbers to support their use.

##### ***Versus placebo***

In one RCT, which included 70 patients using 0.2% desoximetasone for 12 weeks, there was a trend to more regrowth in the treatment group, but the complete regrowth rates were higher in the placebo group [25]. In the second RCT, 34 patients were enrolled in a randomized, double-blind, right to left, placebo-controlled, 24-week study and scored with the alopecia grading scale in accordance with the alopecia areata investigational guidelines [15]. Patients applied clobetasol foam to half their scalp and placebo foam to the other half. Regrowth was seen in 89% of clobetasol-foam-treated head sites versus 11% in placebo-foam-treated sites. Regrowth was partial, with only three patients achieving 75% regrowth. Two patients developed folliculitis. No significant safety concerns were identified [26]. In an observational study, 0.2% fluocinolone aceto-

nide was used under nighttime occlusion. Of the 47 patients, of whom only 28 were evaluable, 17 (61%) achieved a satisfactory clinical response after 6 months [27]. Another observational study involved the use of clobetasol propionate 0.05% under occlusion in 28 patients with alopecia areata totalis and alopecia universalis [28]. Eight (28.5%) patients achieved successful growth 6–14 weeks after the start of treatment.

#### ***Versus each other***

A randomized, controlled, investigator-blinded trial compared betamethasone valerate foam and betamethasone dipropionate lotion in patients with mild to moderate patch alopecia areata [29]. Of the 61 patients evaluated, more than 75% regrowth was achieved in 61% of the patients using betamethasone valerate foam, as opposed to 27% of patients using betamethasone dipropionate lotion.

#### ***Versus topical pimecrolimus***

I found one RCT: 100 consecutive patients were enrolled and randomized into four groups; 30 received 1% pimecrolimus cream, 30 received 0.05% clobetasol propionate cream, 20 received placebo, and 20 had half head treatments with pimecrolimus and clobetasol. There was a trend to worse improvement in the placebo group; however, none of the results achieved statistical significance [30].

#### ***Harms***

Side effects of topical therapy include folliculitis, hypertrichosis, acneiform eruption, and the potential for long-lasting local atrophy and telangiectasia [27].

#### ***Comments***

Potent topical steroids such as clobetasol propionate and betamethasone valerate foam may be of benefit in alopecia areata – particularly the newer formulations and in young children who have relatively thin skin. When used, the treatment should be used continuously for a minimum of 3 months.

#### **Psoralein plus ultraviolet A**

Photochemotherapy involves oral ingestion of psoralen capsules before exposure to ultraviolet A (PUVA) radiation. Treatment is performed three times a week, with the dose of UVA being increased gradually.

##### ***Benefits***

I found no systematic reviews or RCTs. A retrospective audit of 10 years of experience with PUVA showed an effective success rate of 6.3% for disease less severe than the alopecia totalis state [31].

Topical PUVA has been used in a small study of 22 patients with alopecia areata, of whom 36% achieved a regrowth of at least 75% of the treated scalp [32].

#### ***Harms***

Potential risks include sunburn, irritation, accelerated photodamage, and subsequent development of lentigo, nonmelanoma skin cancer, and melanoma [31].

#### ***Implications for clinical practice***

PUVA is likely to be beneficial for only a small number of people. The time commitment involved in attending three times a week for up to 6 months and the potential to induce skin cancer make this therapy unattractive to most patients. PUVA is contraindicated in children because of the possible increase in the risk of later

Figure 57.2 Alopecia areata in an ophiasis pattern.

development of melanoma. Topical PUVA remains an option for this group, but larger scale studies would need to be done to assess the efficacy of this treatment modality.

### **Anthralin (dithranol)**

Anthralin (dithranol) therapy is thought to act as a contact irritant and possibly also as an immunomodulator. Case series suggest that it needs to be applied on a daily basis in a sufficiently high concentration to produce skin irritation.

#### **Benefits**

I found no systematic reviews or RCTs. An uncontrolled, unblinded case series including 68 patients with extensive alopecia areata suggested that up to 25% of patients with patchy alopecia areata may achieve regrowth, compared with 14% with hair loss >75%. New hair growth was generally seen within 3 months if the treatment was effective, although it may take more than double this time to achieve a cosmetically acceptable response [33].

#### **Harms**

Side effects include irritation, scaling, folliculitis, and regional lymphadenopathy. Patients need to protect treated areas from sun exposure. Reversible staining of the skin occurs, and contact with the eyes must be avoided [21].

#### **Comments/implications for clinical practice**

Anthralin is less effective than contact immunotherapy, but readily available and simple to prescribe.

### **Topical minoxidil**

#### **Benefits**

I found no systematic reviews.

#### **Versus placebo**

I found 10 RCTs comparing various concentrations of topical minoxidil with placebo. Early reports suggested a significantly increased frequency of regrowth in patchy but not total alopecia areata [34–40], although subsequent RCTs failed to confirm these results [41,42].

#### **Versus betamethasone**

This incompletely reported study suggested that there was a higher response rate to 5% minoxidil than to 0.005% betamethasone

dipropionate. Both were said to be superior to placebo, but strict numbers and statistical analyses were not reported [43].

#### **Harms**

Systemic side effects are rare with topical minoxidil, and are generally only seen when it is combined with penetration enhancers. When used as monotherapy, the very low serum concentrations of minoxidil after twice-daily topical administration produce no serious systemic hypotensive side effects in minoxidil users [44]. Irritant contact dermatitis is seen in fewer than 10%. Allergic contact dermatitis reaction is rare [34].

#### **Comments**

Minoxidil is unlikely to be beneficial. It is a nonspecific hair-growth stimulant with an unknown mechanism of action. Any effect it may have in alopecia areata is not immunologically based.

### **Cryosurgery**

#### **Benefits**

I found no systematic reviews and no RCTs. I found a single partially controlled case series of 112 patients with patchy alopecia areata covering <25% of the scalp. Seventy-two patients with a total of 237 lesions received a 2–3 s application of a cotton swab dipped in liquid nitrogen [45]. Two freeze–thaw cycles were applied once weekly for 4 weeks. New hair growth was seen in over 60% of the area involved in over 97% of patients treated with liquid nitrogen, which was statistically significant compared with the results of the nontreatment group.

#### **Harms**

Side effects include skin irritation, vesiculation, and blistering. Temporary hyperpigmentation and permanent hypopigmentation can also occur.

#### **Comments/implications for clinical practice**

Cryosurgery is unlikely to be useful. It is not suitable for people with darkly pigmented skin.

### **Aromatherapy**

#### **Benefits**

I found one RCT. The use of aromatherapy was compared with carrier oils alone in a randomized, double-blind, controlled trial over 7 months [46]. Treatment with the essential oils cedarwood, lavender, thyme, and rosemary oils massaged into the scalp every night was seen to be significantly more effective than treatment with carrier oil alone, with an improvement rate of 44%. Although the patients were randomized, treatment groups were small and disease severity was not specified. This result awaits confirmation.

#### **Harms**

None were found.

#### **Comments/implications for clinical practice**

Aromatherapy is unlikely to be successful.

## **What are the management options for severe chronic alopecia areata (including alopecia totalis and universalis)?**

### **Case scenario 57.2**

Michael is 15 years old. At the age of 13, he developed a solitary patch of alopecia areata. Two weeks after an intradermal injection

of triamcinolone, 5 mg/mL, he developed diffuse generalized hair shedding and within 10 days was totally bald (Figure 57.2). Three months later he began to lose his eyebrows and eyelashes, and ultimately every hair on his body was lost. Unable to cope with the teasing at school, he had not attended for the previous 8 weeks. A general assumption by his teachers was that he was away from school receiving chemotherapy.

## Topical immunotherapy

### Benefits

I found one systematic review, no RCTs, but numerous case series [22,23,47,48]. Response rates for patients with severe disease vary from 2 to 50%.

### Harms

These are identical to those listed for topical immunotherapy for patchy alopecia areata.

### Comments/implications for clinical practice

In all the case series reported, patients with severe alopecia areata and in particular alopecia totalis/universalis, responded less frequently to topical immunotherapy. While the response rates are lower when patients have severe alopecia areata, these patients are often highly motivated and prepared to trial the therapy regardless. A minimum trial of 6 months is required. Initial therapy to half the head and only treating the opposite half after demonstrable regrowth is advocated.

## Systemic corticosteroids

Oral prednisolone or dexamethasone or intravenous methylprednisolone will stimulate hair regrowth in most, but not all, patients if used at a high enough dosage. It has been suggested that the initial dose threshold for oral prednisolone is 0.8 mg/kg, which is then decreased slowly over 6–8 weeks. Pulse therapy can also be considered in these patients.

### Benefits

I found no systematic reviews. A placebo-controlled study evaluated the efficacy of pulse oral prednisolone therapy in severe alopecia areata. The regimen involved 200 mg oral prednisolone once a week for 3 months. Of the 84 patients recruited, 40% experienced significant hair regrowth at the end of 3 months, compared with none in the placebo group. Indicators of poor outcome in this study included atopy, nail involvement, multiple episodes, and prolonged duration of disease (more than 2 years). Relapse rates after treatment were not commented on in this study [49]. Numerous case series have been reported as well, but these are not directly comparable because of different patient selection, dose scheduling, and duration of therapy. Winter *et al.* [50] reported a case series of 18 patients with prednisolone on alternate days at doses adjusted according to the clinical response (usually two to four times the daily adrenal replacement dose, and up to 80–120 mg on alternate days in unresponsive patients). A progressively increasing dose of prednisolone was required to maintain cosmetically acceptable hair growth, and most patients experienced rapid hair loss after discontinuation of prednisolone therapy [50]. Oral steroids used in combination with topical and intralesional steroids have shown benefit in nonrandomized trials [51]. The use of topical and intralesional steroids allowed for more rapid lowering of oral doses, and thus minimization of side effects. Seven of 15 patients treated with oral

steroids showed regrowth of most or all of their hair, with an average remission of 32 months [52].

### Harms

Weight gain and Cushingoid facies are the main side effects [51]. Prolonged therapy with oral corticosteroids may retard growth, demineralize bones, and lead to premature fusion of the bony epiphyses. Nausea and polymenorrhea can occur with pulsed steroid therapy [52].

### Comments/implications for clinical practice

Many patients who are offered systemic corticosteroids decline to take them because of the potential systemic side effects and the high relapse rate. Around 70–80% of patients do regrow hair following a brief course of systemic corticosteroids, but over 50% of those who regrow hair with systemic corticosteroids relapse on dose reduction or within a few months of ceasing therapy. While around 35–40% of patients have sustained remissions following a course of treatment, a similar number will either have to accept the relapse or consider long-term systemic treatment. Some patients can be managed with low-dosage systemic corticosteroids (5–10 mg per day) or with a steroid-sparing agent. Long-term high-dose systemic corticosteroids are not desirable and are not recommended for alopecia areata. In view of the limited therapeutic alternatives, systemic corticosteroid use is attractive, but clinicians must contemplate how the dosage will be weaned and relapses managed. Patients who require more than 6 weeks of systemic corticosteroids should receive general measures to prevent bone demineralization [53].

## Ciclosporin

### Benefits

I found no systematic reviews or RCTs for oral ciclosporin. In a small case series, six patients received oral ciclosporin, 6 mg/kg per day for 12 weeks [54]. All patients had some regrowth, but cosmetically acceptable regrowth occurred in only two of five patients with alopecia totalis/universalis and in the single patient with patchy alopecia areata. All patients had relapsed within 3 months of stopping therapy. A randomized study of 26 patients with alopecia totalis or universalis compared topical 10% ciclosporin daily with photochemotherapy three times a week and intravenous thymopentin, 50 mg three times a week every 3 months over 9 months [24]. All of the patients had previously been unresponsive to sensitizing therapy for at least 12 months. None of the patients in the study had any cosmetic clinical improvement by the end of the study.

### Harms

In the case series of six patients receiving oral ciclosporin, the side effects were mild and transient [55]. Davies and Bowers. reported on two patients who had first developed alopecia areata while taking ciclosporin [55]. While the precise mechanism is unknown, alopecia areata can occur in patients who are at least partially immunosuppressed.

### Comments/implications for clinical practice

The effectiveness of oral ciclosporin for alopecia areata is unknown. A dosage of 6 mg/kg per day is a high dose of ciclosporin and would require very careful monitoring for renal and other toxicity. The relapse rates on discontinuation of therapy are high, and there is a reluctance to use long-term therapy because of cost and cumulative side effects. Topical ciclosporin is ineffective.

## Methotrexate

### Benefits

I found no systematic reviews or RCTs for oral methotrexate. A number of retrospective case series, using either methotrexate alone or in combination with corticosteroids, including one in children, have suggested a clinical response in a proportion of patients [56,57].

### Harms

The effectiveness of methotrexate for alopecia areata is unknown. The average maximum dosage of 18.9 mg per week is high and would require very careful monitoring for hepatic and other toxicity.

## Azathioprine

### Benefits

I found no systematic reviews or RCTs for oral azathioprine. Azathioprine is commonly used as a steroid-sparing agent in the treatment of autoimmune disease. In one case series, where 20 patients were treated with 2 mg/kg for 6 months, statistically significant improvement in the mean hair score compared with baseline was seen. There was no placebo group control in this study [58].

### Harms

Azathioprine can have serious hemotological toxicity. Pretreatment estimation of the serum trimethypurine methyl transferase is available in most countries and can be used to estimate risk of myelosuppression.

## Other therapies

### Benefits

Alefacept, efaluzumab, etanercept, and adalimumab are not effective in promoting hair regrowth in alopecia areata [59]. In fact, there are numerous case reports of alopecia areata developing in patients being treated with biologics.

Inosine pranobex at a dosage of 50 mg/kg per day for 6 months was ineffective in one series [60] and slightly helpful in another [61].

The combination of SADBE immunotherapy at weekly intervals and interferon alpha  $3.0 \times 10^{-6}$  IU intramuscularly, daily for 15 days, three times a week for 2 weeks, then once a week for 2 months, appeared to be better than SADBE alone [62].

Sulfasalazine was reported as useful in one case series, but this has not been reproduced [63].

### Harms

Flu-like symptoms were observed in patients receiving interferon alpha [62]. No clinically significant side effects attributable to inosine pranobex were reported [61].

### Comments/implications for clinical practice

The low response rate in alopecia totalis should be explained to patients before commencing experimental treatments.

## What are the treatment options for alopecia areata in children?

### Case scenario 57.3

Anthony developed 20-nail dystrophy at the age of 30 months. Six months later he developed a single patch of alopecia areata. Nightly

topical application of 0.05% clobetasol dipropionate cream to the patch led to regrowth within 6 weeks, with no obvious cutaneous atrophy. There was some mild associated hypertrichosis of the forehead, which resolved within 6 months of the cream being stopped.

Anthony had no family history of alopecia areata, and no history of atopy. Three years later he presented again with four patches of alopecia areata, each about 3 cm in diameter.

## Topical corticosteroids

Topical corticosteroids are discussed under the section on patchy alopecia areata.

### Benefits

In an observational study of 48 patients, children aged 3–10 years had a higher response rate to topical corticosteroids than adults did [27].

## Topical immunotherapy

### Benefits

I found no systematic reviews. I found one RCT that involved small numbers of children. Tosti *et al.* [18] compared SADBE, diphencyprone, minoxidil, and placebo, finding a significant relationship between the age of the patients and the results. Complete hair regrowth was seen in 71.3% of adults, but in only 38.9% of children.

I found two case series. Schuttelaar *et al.* [64] treated 26 children with diphencyprone weekly for a period of 3–12 months. Sixteen subjects had alopecia areata totalis, and the others had patchy disease only. Eighty-four percent of the children showed hair regrowth, 32% of the total being cosmetically acceptable. Where treatment failed (0–5% hair growth), it was recommended not to continue treatment for longer than 1 year, as hair growth is not promoted by continued treatment. Orecchia and Malagoli [65] treated 28 unresponsive children under the age of 13 years with SADBE for 12 months. Thirty-two percent of the patients achieved complete or cosmetically acceptable regrowth, and a further 21% achieved significant regrowth.

### Harms

Schuttelaar *et al.* noted the problem of psychological dependence on the diphencyprone in certain children and parents, who asked to continue treatment after regrowth had been achieved, fearing a relapse [64]. As with previous studies, itching, erythema, and scaling were noted side effects. Swelling of regional lymph nodes was common and disappeared after discontinuation of treatment [65].

### Comments/implications for clinical practice

Topical immunotherapy has been used in children as young as 4 years by a number of investigators. Taking into consideration that the development of alopecia areata before the age of 10 years is an independent adverse prognostic indicator, side effects and efficacy appear to be similar to those seen in adults. Efficacy is also influenced by the extent of the disease, associated nail changes, and atopy.

## Topical minoxidil

Topical minoxidil has not been tested in children. Systemic absorption and systemic side effects may be more likely to occur in children.

## Key points

### Patchy alopecia areata

- The spontaneous remission rate in alopecia areata is high, which makes evaluation of treatment in the absence of RCTs very difficult.
- No treatment alters the natural history of alopecia areata.
- I found no good evidence in support of nondrug treatment.
- Small RCTs have shown that intralesional injection of triamcinolone acetonide can effectively stimulate regrowth of patchy alopecia areata. Transient atrophy is common. Treatment can be repeated at 4–6-weekly intervals if necessary. I was not able to find data on long-term efficacy.
- One RCT demonstrated that potent topical corticosteroids are marginally more effective than placebo in patchy alopecia areata when used continuously for a minimum of 3 months. In observational case series, children between the ages of 3 and 10 years appear most likely to respond.
- I found one systematic review based on case series on the use of topical immunotherapy. A number of studies have demonstrated unilateral hair regrowth after unilateral treatment. This protocol has been favored for evaluation of topical immunotherapy because of the inability to blind patients. The systematic review of published case series on the use of topical immunotherapy with diphenylcyclopropenone concluded that 50–60% of patients achieve a worthwhile response. Patients with limited disease have higher response rates than those with alopecia totalis/universalis.
- I found insufficient evidence on the use of topical minoxidil, topical anthralin therapy, PUVA, aromatherapy, cryosurgery, and ciclosporin A.

### Alopecia totalis/universalis

- The prognosis for spontaneous or assisted regrowth is poor.
- In all RCTs, the extent of disease is an adverse prognostic factor for regrowth.
- Systemic corticosteroids can be used, but not for prolonged periods – a tapering schedule and a plan for managing relapses should be thought of from the outset.

### Childhood alopecia areata

- In most RCTs, an early age of onset is an adverse prognostic factor for regrowth.
- Topical corticosteroids therapy may be more effective in children than in adults.
- Intralesional injection of corticosteroids is unsuitable for use in children. Most children will not tolerate repeated injections, limiting the usefulness of intralesional corticosteroids.
- Prolonged therapy with oral corticosteroids may retard growth, demineralize bones, and lead to premature fusion of the bony epiphyses.
- PUVA is contraindicated in children because of the possible increase in risk of future development of melanoma.
- Topical PUVA can be tested in this group.

# Evidence-based treatment of hirsutism

Ulrike Blume-Peytavi and Natalie Garcia-Bartels

Department of Dermatology and Allergy, Charité-Universitätsmedizin Berlin, Berlin, Germany

## Background

### Definition

Hirsutism is defined as the presence of excess terminal (coarse) hairs in females in a pattern typically seen in adult males [1,2]. Hypertrichosis, unlike hirsutism, is independent of androgen influence and is characterized by the superfluous and uniform growth of nonterminal (vellus) hair over the body, particularly in nonsexual areas [3].

### Incidence/prevalence

Approximately 5–10% of women of reproductive age in the general population are hirsute (assessed as having a Ferriman–Gallwey (FG) score of  $\geq 8$ ) [1–4]. The FG score is a clinical score evaluating and quantifying the amount of hair growth in 11 different body areas [5].

### Etiology

Hirsutism is usually the result of an underlying adrenal, ovarian, central endocrine, or peripheral abnormality. Elevated secretion of androgens, increased bioavailability of testosterone, and increased sensitivity of hair follicles to androgens all contribute to the condition [1,6]. The most common cause of androgen excess is polycystic ovary syndrome (PCOS); 70–80% of patients with androgen excess demonstrate hirsutism [2]. Up to 4% of women are affected by PCOS, in whom hirsutism is the most common clinical manifestation of the elevated androgen levels [7]. Hirsutism is deemed idiopathic when it develops in the absence of excess androgen levels and in conjunction with normal ovulatory function; these findings account for less than 20% of hirsute women [8]. Other causes of androgen excess, such as nonclassic congenital adrenal hyperplasia (1.5–2.5% of cases) [9,10] and androgen-secreting tumors (0.2% of cases) are less common causes of hyperandrogenism. Cushing's syndrome, hyperprolactinemia, acromegaly, and thyroid dysfunction are other rare but possible causes, and certain prescribed drugs, such as anabolic or androgenic steroids, can also cause hirsutism [3,6,11].

### Prognosis

If the underlying cause of hirsutism can be well controlled (e.g., ovarian or adrenal dysfunctions), the hirsutism may resolve or at least be well controlled. As no cause can be identified in idiopathic hirsutism, its prognosis may be poorer, and resolution will depend on hair removal by physical, chemical, or electrical means. Women presenting with hirsutism due to PCOS may not respond well to epilation treatments unless the specific underlying cause is addressed. The correct evaluation and diagnosis of female hirsutism, coupled with the use of combination therapy, can provide adequate results in many patients, although long-term studies are needed to confirm current findings.

### Diagnostic tests

*Hirsutism is a clinical diagnosis.* A European consensus was published on the evaluation of women presenting with excessive hair growth based on a systematic review and discussion of current clinical practice across Europe. The interdisciplinary European expert group developed a diagnostic questionnaire for daily practice [11]. Diagnosing hirsutism requires a medical history, physical examination, and investigations to screen for any risk factors for virilizing disorders, PCOS, or hormonal imbalances. It is also important to consider whether any of the patient's current medications could potentially cause or exacerbate the hirsutism. In the case of rapidly progressing hirsutism, or when there is evidence of further virilization, it is important to eliminate the presence of an androgen-secreting tumor. The severity of hirsutism can be evaluated using the FG score [5,11], although caution is required, as it is a subjective assessment measure and not as readily applicable in women of Asian origin. A popular adoption of the FG evaluates nine, rather than 11, body sites [1,3]. Each body site is scored from 0 to 4 on the basis of the number of coarse hairs present. A score of 8 or more is consistent with the diagnosis of hirsutism. The FG score is also used in monitoring the patient's individual responses to treatment and is helpful for the clinician in evaluating the patient's degree of hirsutism.

Companion Website: [www.evidencebasedseries.com/dermatology](http://www.evidencebasedseries.com/dermatology)

In patients with moderate or severe hirsutism, or in whom other risk factors are present, a screening test for androgen excess is an early morning:

$$\text{Free androgen index (FAI)} = \frac{\text{Total testosterone} \times 100}{\text{Sexual hormone binding globulin (SHBG)}}$$

In addition, dehydroepiandrosterone sulfate (DHEAS) should be measured while performing hormonal diagnostic work-up. Whereas normal total testosterone and DHEAS readings in patients with regular menstrual cycles support the diagnosis of idiopathic hirsutism, normal levels do not eliminate peripheral androgen excess. Hair follicles and sebaceous glands can synthesize androgens de novo or convert circulating androgens to more potent ones. Furthermore, a monthly curve of basal temperature, in combination with a measurement of 17-OH-progesterone (days 20–24), should help exclude the presence of an asymptomatic anovulatory menstrual cycle or late onset adrenogenital syndrome. In patients with hirsutism and irregular menstrual cycles, a thorough endocrinological work-up is essential. The following laboratory tests should be undertaken: 17-OH-progesterone, estradiol, SHBG, prolactin, testosterone (total and free), DHEAS, cortisol, thyroid-stimulating hormone, and serum glucose. Mildly elevated total testosterone levels or FAI unsatisfactory responses to treatment, or the suspicion of another disorder all warrant an early-morning free plasma testosterone test [10,11]. Severely raised total testosterone ( $>19 \mu\text{mol/L}$ ) is suggestive of an underlying neoplasm, with elevated levels of DHEAS indicating an adrenal source. Ultrasonography of the adrenal gland and/or pelvic region can also be helpful in the diagnosis of hirsutism. In the case of PCOS in particular, imaging the ovaries and performing hormonal tests (i.e., the luteinizing hormone/follicle-stimulating hormone ratio) can help confirm or refine the diagnosis.

### Aims of treatment

The aim of treatment is to treat any causal hormonal imbalance and decrease the excessive hair growth of hirsutism, thereby positively affecting the patient's quality of life [12]. The primary goal in the management of hirsutism is to achieve central or peripheral androgen suppression using three groups of drugs: inhibitors of androgen production (oral contraceptives (OCPs), gonadotropin-releasing hormone analogues), peripheral androgen blockers (cyproterone acetate, flutamide, finasteride, and spironolactone) and insulin sensitizing agents (metformin). A combination of pharmacological, physical and chemical treatment regimens can be used, depending on the particular case, to achieve the optimum result for the patient.

### Relevant outcomes

Outcome measures to evaluate the management of hirsutism include clinical evaluation using the FG score, hair density, thickness, and length, or questionnaires [11]. There are few studies employing objective measurements such as a phototrichogram and global photographic evaluation to quantify hair growth changes. In addition, well-designed controlled studies that include assessment of patients' quality of life are needed.

## Questions

### What are the effects of treatments for a woman with idiopathic hirsutism?

#### Case scenario 58.1

A 25-year-old woman has suffered from excessive facial hair growth since puberty (Figure 58.1). She plucks and waxes regularly to remove unwanted facial hair and has tried electroepilation, which resulted in mild scarring. She is unhappy with the frequency with which she has to carry out these hair removal techniques and with the time involved in treating the relatively large area affected. Dermatological assessment revealed a modified FG score of about 18, with hypertrichosis mainly on the face and less on the upper legs. No other signs of hyperandrogenemia were noted. Following consultation with a gynecologist, PCOS, nonclassic adrenal hyperplasia, androgen-secreting tumors, and prolactinoma were excluded as potential causes of the patient's facial hirsutism.

### Antiandrogens

#### Efficacy

**Cyproterone acetate** There is one systematic review of nine randomized controlled trials (RCTs) using cyproterone acetate to treat hirsutism [13]. Cyproterone acetate combined with estradiol resulted in a subjective improvement in hirsutism in comparison with placebo. No clinical differences in outcome were found between cyproterone acetate and the other medical therapies (ketoconazole, spironolactone, flutamide, finasteride, and gonadotropin-releasing hormone analogues). However, the different drug

**Figure 58.1** A 25-year-old woman with excessive facial hair 2 weeks after waxing.

therapies lead to endocrinological differences in androgen and estrogen levels.

A well-designed ( $n = 134$ ) RCT compared three treatment regimens with cyproterone acetate or drospirenone containing combined OCPs plus spironolactone or cyproterone acetate in women with moderate and severe hirsutism [14]. All three treatment regimens significantly decreased the modified FG hirsutism score, but without significant difference between groups.

**Chlormadinone acetate** The use of combined OCPs containing chlormadinone acetate (CMA) or cyproterone acetate plus ethinyl estradiol (EE) was shown to produce an improvement of patients' hirsutism in 36% of cases [15]. CMA-containing combination OCPs have proved similarly effective as cyproterone acetate/EE in women with androgen-related skin and hair conditions. A small single-center clinical study on young nonobese women with PCOS ( $n = 15$ ) receiving a six-cycle treatment with EE30 CMA demonstrated an efficacious improvement of hyperandrogenic symptoms compared with a matched age group of nonobese no OCP-PCOS women [16]. Hirsute women showed significant improvement of sexual life quality and self-esteem evaluated in a small noncontrolled clinical study of hirsute women receiving for 9 months an OCP containing EE/CMA [17].

**Spironolactone** One systematic review of the use of spironolactone in the treatment of hirsutism and/or acne was found, which included nine RCTs [18]. The review concluded that 6 months' treatment with spironolactone 100 mg/day was associated with a statistically significant subjective improvement in hair growth and a decrease in the FG score in comparison with placebo. Overall, the authors stated that individual study data indicated some superiority of spironolactone over other drugs, but owing to small and scarce studies these results cannot be generalized.

Spironolactone 100 mg/day in the treatment of hirsutism has also been shown to be more effective than finasteride 5 mg/day and low-dosage cyproterone acetate 12.5 mg/day (first 10 days of cycle) up to 12 months after treatment [6]. An open-label trial of 109 women demonstrated that low-dose spironolactone successfully improved hirsutism in 72% of women treated [14]. Another open-label trial comparing the efficacy of spironolactone and metformin in 82 young women with PCOS found that the two drugs were similarly effective in the management of PCOS, although spironolactone was more effective in the treatment of hirsutism [6].

A systematic review and meta-analysis on RCTs investigating antiandrogens for the treatment of hirsutism with 12 eligible RCTs (18 comparisons) of relative low methodological quality concluded that there is only weak evidence that antiandrogens are mildly effective agents for the treatment of hirsutism [19]. For clinical practice it is important to note that spironolactone or finasteride in combination with contraceptives or flutamide with metformin appear superior to monotherapy with contraceptives and metformin, respectively.

**Flutamide and bicalutamide** Flutamide was found to be more effective than finasteride in the treatment of hirsutism. An RCT comparing low-dose flutamide, finasteride, ketoconazole, and cyproterone acetate–estrogen regimens in the treatment of 66 hirsute women showed that flutamide and cyproterone acetate, combined with estradiol, were the most effective and well tolerated of the treatments studied [20]. An RCT compared the efficacy of flutamide and spironolactone plus Diane 35 (cyproterone), Dianette (2 mg cypro-

terone acetate and 35 µg EE) in the treatment of hirsutism [21]. In this study of 80 patients, the FG score decreased significantly and to similar levels in both treatment groups, suggesting that the two therapies are similarly effective in the treatment of hirsutism.

Long-term efficacy and tolerability of flutamide evaluated in a prospective observational study showed that although flutamide was very effective in treating hirsutism, frequently occurring adverse effects lead to low long-term compliance [22].

The efficacy of low-dosage bicalutamide (25 mg/day) in the treatment of hirsutism was investigated in a small open-label study of 42 women [23]. Clinical improvement in the degree of hirsutism was observed in all patients, with the mean modified FG score decreasing from  $22.0 \pm 5.1$  to  $8.6 \pm 3.5$  after 6 months' treatment ( $P < 0.0001$ ). Hair density was visibly reduced; with a reduction in the FG score of  $41.2 \pm 11.4\%$  seen at 3 months and of  $61.6 \pm 11.1\%$  at 6 months.

### Drawbacks

The spectrum of adverse effects of antiandrogens includes headache, nausea, weight gain, depression, fatigue, breast symptoms, menstrual irregularity, and sexual dysfunction, but there is not enough evidence to compare the differences of adverse events between the different therapeutic options [13]. Spironolactone may lead to polymenorrhea and hyperkalemia [6].

### Comments/implications for clinical practice

Antiandrogens can produce statistically significant improvement in hair growth and decreases in FG scores. However, small study sizes and a lack of standardized assessment and objective measurements of improvements in hirsutism mean that the results are difficult to interpret. Clinical impressions of treating doctors are thinning of hair shaft diameter and reduction of hair regrowth rate leading clinically to improved, but most often not satisfactory, results for the concerned women. Further studies are required in order to compare efficacy and safety profiles between drug therapies for hirsutism using objective measurements such as hair density, hair thickness, and hair growth rate. Antiandrogens should always be administered in women of childbearing age along with reliable contraception owing to the risk of feminization of a male fetus in case of pregnancy under antiandrogens.

### Enzyme inhibitors: finasteride

#### Efficacy

The 5 $\alpha$ -reductase inhibitor finasteride has been evaluated for the treatment of hirsutism in many randomized and observational trials. The results have shown that finasteride can lower hirsutism scores by 30–60%, in addition to reducing the average hair diameter [19,24].

In an RCT comparing low-dose flutamide, finasteride, ketoconazole, and cyproterone acetate–estrogen regimens in the treatment of 66 hirsute women, finasteride treatment significantly reduced FG scores (–44%), hair diameter (–16%), and daily hair growth rate (–27%) [25]. Although finasteride had the slowest onset of action of the drugs studied in the trial, it was still highly effective, with the hair diameter at the end of treatment similar to that in the other therapies studied. Furthermore, finasteride was associated with fewer side effects.

In a similar trial of 41 women with idiopathic hirsutism, the short-term results of treatment with cyproterone acetate, finasteride, and spironolactone were similar, but spironolactone demonstrated a higher efficacy over a longer time period [24]. In a small

clinical study, investigation of the efficacy and safety of finasteride (5 mg/day) plus flutamide (125 mg/day) combination therapy in unselected women with hirsutism ( $n = 44$ ) revealed that flutamide is more effective than finasteride and the combination of these two drugs is not better than flutamide alone, but better than finasteride in hirsute women [26].

### **Drawbacks**

Finasteride may cause breast enlargement, breast tenderness, and rash.

### **Comments/implications for clinical practice**

Although finasteride has been shown to be effective in the treatment of hirsutism, it is not licensed for the condition. It is also contraindicated in women who wish to become pregnant or are potentially pregnant, as it can cause feminization of the male fetus. Women treated with finasteride should therefore also be given appropriate and safe contraception.

## **What are the effects of topical treatments for facial hirsutism?**

### **Enzyme inhibitors: eflornithine**

#### **Efficacy**

The efficacy of eflornithine in the treatment of facial hirsutism has been evaluated in two multicenter, randomized, double-blind, placebo-controlled trials including 596 patients, which were not published separately but only as pooled analysis. [27]. Facial hirsutism significantly improved within 8 weeks of treatment with eflornithine. After 24 weeks of treatment, 70% of the patients treated showed some improvements, with 32% of patients said to be clinically improved in comparison with only 8% in the placebo group.

Combination therapy with eflornithine cream plus laser epilation can be effective and results in more rapid hair removal in comparison with laser monotherapy [28,29]. Further long-term prospective trials are needed in this area. In addition, use of topical eflornithine has been shown to significantly improve women's emotional burden by excessive hair compared with those receiving placebo [30].

### **Drawbacks**

The most common adverse events associated with eflornithine treatment are mild and skin related, including burning, tingling, stinging, erythema, and rash at the site of application (2–7% over a 12-month observation period. All of these are mild, transient, and resolve without dose reduction and without medical intervention.

### **Comments/implications for clinical practice**

Eflornithine is simple to apply and can therefore be readily incorporated into patients' existing daily skin-care regimens. Treatment with eflornithine can be used alongside medical treatments or mechanical hair removal methods. Treatment with eflornithine is not indicated during pregnancy and lactation. It should be noted that the benefits of treatment start to diminish 8 weeks after therapy is discontinued.

## **What are the effects of alternative methods of epilation for treating hirsute women?**

### **Electroepilation**

#### **Efficacy**

No systematic reviews or RCTs were found. Richards *et al.* reported the results of over 35 000 h of electroepilation treatment in 281

women over a 4-year period [31]. The study found that electroepilation was beneficial in controlling facial hirsutism, with 93% of patients showing improvement, with no evidence of scarring. The best results were obtained when electroepilation was combined with medical treatment to resolve any androgen excess. Based on observations from 13 years and 140 000 h of experience, the blend method is reported to be the most effective method for permanent hair removal [32]. In the blend method, heat is created through the modulation of a high-frequency current, leading to thermal injury of the hair follicle with subsequent destruction. Although permanent hair removal can be achieved in some cases, the success of the technique ultimately relies on the skill of the operator.

### **Drawbacks**

Electroepilation can cause temporary pain, erythema, and edema. Scarring, keloid formation, and postinflammatory pigment changes are also possible. There is insufficient evidence to recommend electroepilation as a method superior to other epilation techniques.

### **Comments/implications for clinical practice**

Electroepilation may take up to 24 months to be effective, and its success is dependent on many factors, such as previous treatments, hair type, and operator skill. There is an increased risk of scarring if probing is inaccurate, if too much current is used, or if hygiene or aftercare are inadequate.

### **Photoepilation**

#### **Efficacy**

One systematic review was found including 11 RCTs, none of which were of high quality. There appeared to be a short-term effect of approximately 50% hair reduction with alexandrite and diode lasers up to 6 months after treatment, whereas there was little evidence for an effect with intense pulsed light, neodymium:yttrium-aluminum-garnet (Nd:YAG) or ruby lasers [33]. Long-term hair removal was not reported for any treatment. According to the authors, pain, skin redness, swelling, burned hairs, and pigmentary changes were the most frequent reported adverse effects.

In an RCT of 88 women with PCOS-related hirsutism, 6 months of photoepilation significantly reduced the severity of facial hair and lowered depression scores and anxiety ratings compared with controls [33]. In a retrospective study using a solid-state 100 nm pulsed near-infrared diode laser system in 242 patients, retrospective analysis of patient questionnaires revealed that a reduction in pigmented hair was achieved after an average of 1.97 treatments and maintained for a mean period of 8.1 months [34,35]. The habitual hair-plucking interval was also increased from a mean of 3.69 days before treatment to 15.19 days after laser epilation.

In an RCT of single treatment sessions using an alexandrite laser, a 40% reduction in hair growth was seen 6 months after treatment [35]; and in a prospective trial using an Nd:YAG laser, a single treatment session with the laser and topically applied carbon dye resulted in greater hair reduction in comparison with laser alone [36].

Comparison of efficacy and safety of intense pulsed light (IPL) versus long-pulsed diode laser (LPDL) in a well-defined group of hirsute women ( $n = 31$ ) with normal testosterone levels showed that patients responded equally well to IPL and LPDL treatments with reduction of excessive facial hair growth but with declining efficacy over 6 months [37].

In a small RCT in hirsute women, use of IPL proved to be an efficient tool to eliminate white hair, an effect which could be

**Figure 58.2** Central hair thinning in a 32-year-old woman with PCOS, obesity, and hyperinsulinemia.

enhanced by coloring the white hair prior to use of IPL technology [38].

#### **Drawbacks**

Photoepilation can cause edema, erythema, pain, hypopigmentation, and hyperpigmentation. Rarely, increased hair growth at the treated site has been reported.

#### **Comments/implications for clinical practice**

Further long-term RCTs and comparative studies are needed to establish the benefits of photoepilation. With the development of lasers and IPL technology to specifically target hair follicles, large areas can be treated rapidly, and long-term hair-free intervals can be achieved, although permanent hair loss is rare.

### **What are the effects of treatments for women with hyperinsulinemia?**

#### **Case scenario 58.2**

A 32-year-old woman consulted her dermatologist for scalp hair loss (Figure 58.2). Clinical examination revealed female-pattern hair loss. She reported that she felt uncomfortable in the public due to her excessive body hair and that recent weight gain had added to her distress. Her menstrual cycle was irregular, with cycles ranging from 25 to 38 days. She was referred to a gynecologist who diagnosed PCOS. The patient's body mass index (BMI) was approximately 31, and investigations revealed hyperinsulinemia.

#### **Insulin-sensitizing agents**

##### **Efficacy**

A systematic review and meta-analyses of RCTs of metformin or thiazolidines for the treatment of hirsutism for which 16 studies of low to very low quality were eligible demonstrated that insulin sensitizers provide limited or no important benefit for women with hirsutism [36].

There is one systematic review including six trials, four of which compared metformin versus OCP (104 participants) and two of which compared OCP combined with metformin versus OCP alone (70 participants). Limited data demonstrated no evidence of difference in effect between metformin and the OCP on hirsutism

and acne. However, there was a benefit for the women after a 12-month treatment with the OCP with an improvement in menstrual pattern and serum androgen levels compared with metformin; but metformin treatment results in a reduction in fasting insulin and lower triglyceride levels than with the OCP [39].

A small RCT of metformin was carried out to assess the effects of metformin on hair growth [6]. Sixteen women with PCOS and hirsutism were enrolled into a 14-month double-blind, placebo-controlled crossover study. Throughout the study, the severity of hirsutism was assessed using the FG score, patient self-assessment, and growth velocity. Metformin treatment led to significant improvements in the FG score and patient self-assessment. Growth velocity in millimeters per day at the end of each phase was also improved. The authors concluded that metformin treatment in this patient group led to a clinically and statistically significant improvement in hair growth in comparison with placebo.

An RCT with hirsutism as the primary end point compared the efficacy of metformin with combined EE and cyproterone acetate [40]. Patients with PCOS ( $n = 52$ ) received either metformin (500 mg, three times daily) or Diane 35, Dianette (EE 35 µg and cyproterone acetate 2 mg) for 12 months. Objective and subjective methods of evaluating hirsutism and patients' self-assessment scores were used. Metformin treatment resulted in greater improvements in the FG score and patient self-assessment scores. Both treatments were moderately effective in reducing the hair diameter at multiple anatomical sites. The data suggest that hirsutism may be effectively treated by reducing hyperinsulinemia.

In an open-label study comparing the efficacy of metformin with spironolactone in 82 women with PCOS, both treatments significantly improved hirsutism scores, but spironolactone was more effective in slowing hair growth [6].

Recently, a prospective observational study investigated 45 lean PCOS patients who received EE/drospirenone (DRSP) ( $n = 25$ ) or EE/DRSP plus metformin ( $n = 20$ ) and 45 BMI-matched healthy controls. EE/DRSP alone or in combination with metformin improved clinical and biochemical hyperandrogenism in lean PCOS. Insulin sensitivity was not affected by EE/DRSP alone, in contrast to a combination of EE/DRSP with metformin [41].

#### **Drawbacks**

Metformin can cause nausea and vomiting, taste disturbances, and loss of appetite. Rosiglitazone can cause anemia, hypercholesterolemia, flatulence, nausea, vomiting, and gastritis. In September 2010 the European Medical Agency decided to suspend the market authorization of rosiglitazone, while the US Food and Drug Administration decided to restrict the use of rosiglitazone, because rosiglitazone might be associated with an increased risk of ischemic heart disease [42].

#### **Comments/implications for clinical practice**

There are several small RCTs suggesting significant improvement; however, they are based upon a low number of subjects. Even if no general conclusions for clinical practice can be drawn from such small RCTs, their validity should be checked in larger controlled studies as the primary outcome of reduction in hair growth is key for counseling patients affected by hirsutism.

The hair-growth cycle is relatively long, and the potential effects of the drugs studied should not be evaluated with less than 12 months of treatment. Future trials of longer duration, therefore, need to be carried out in order to provide adequate data to inform clinical practice.

## Key points

- Combined OCPs containing cyproterone acetate plus EE or CMA are effective for treating women with idiopathic hirsutism.
- Insulin-sensitizing agents (e.g., metformin) are effective for treating hirsute women with PCOS. Metformin led to a greater improvement in hirsutism compared with EE 35 mg plus cyproterone acetate 2 mg or placebo.
- Photoepilation has been shown to reduce the density of dark hairs. Better results were obtained with alexandrite, diode, or ruby lasers than with the Nd:YAG laser.
- Topical use of the enzyme inhibitor eflornithine has been clinically proven to slow down the rate of hair growth. Combination therapy with eflornithine cream and laser epilation results in better hair removal than laser monotherapy.

# Focal hyperhidrosis

Kave Shams<sup>1</sup> and Berthold Rzany<sup>2</sup>

<sup>1</sup>Alan Lyell Centre for Dermatology Glasgow, Western Infirmary, Glasgow, UK

<sup>2</sup>RZANY & HUNDm, Privatpraxis für Dermatologie und Ästhetische Medizin, Berlin, Germany

## Background

Sweating fulfills several important functions. Sweat is produced by eccrine and apocrine sweat glands, of which the eccrine type is the most numerous. Sweating plays a key role in thermoregulation, whilst localized sweat production enhances grip of, for example, palms. Sweat produced by apocrine sweat glands (e.g., axillae, groin) accounts for odor generation, though their role in humans is not entirely clear. Excessive sweating, or hyperhidrosis, can have a profoundly detrimental physical and psychological impact on those affected [1,2]. Hyperhidrosis is possibly undertreated, with many of those affected never seeking professional help [3].

## Definition

The amount of sweating depends on, for example, environmental factors and the physical and emotional state of the patient [4]. Consequently, there are no widely accepted diagnostic cut-offs for diagnosing hyperhidrosis. This limitation remains a great challenge for those diagnosing, treating, and researching the condition. Sweating is typically categorized as being focal (commonly axillary, palmar, and/or plantar) or generalized, and either primary (i.e., idiopathic, when it tends to be focal) or secondary (where there is an identifiable underlying cause, where the sweating is often generalized).

## Incidence/prevalence

An epidemiological study from the USA estimated the prevalence of hyperhidrosis at 2.8%, most frequently affecting those between 18 and 54 years of age with an average age of onset of 25 years [3]. Studies from North America and South Korea suggest that those with a positive family history have a lower age of onset [4,5]. Results from various epidemiological studies are variable, which possibly reflects inconsistencies in the methods of diagnosis and inherent heterogeneity between different study populations.

There is no reliable evidence for gender differences in terms of incidence/prevalence, although there is some evidence for differences in the types of hyperhidrosis with which people present [4].

## Etiology

Generalized hyperhidrosis can be primary or secondary to a range of underlying conditions such as malignancies, endocrine abnormalities, infections, or neurological diseases. Focal hyperhidrosis, in contrast, is most commonly a primary condition, although there are exceptions, such as Frey's syndrome (gustatory sweating secondary to facial nerve damage, commonly following parotid gland surgery) [6]. The high rate of affected first-degree relatives amongst those with hyperhidrosis has led to suggestions of a genetic basis [7]. The cause of primary hyperhidrosis remains unclear in most instances, but there is limited evidence that the eccrine glands in those with hyperhidrosis differ functionally from those unaffected by the condition [8].

## Prognosis

No good data are available on the prognosis of focal hyperhidrosis.

## Diagnostic tests

In the absence of reliable diagnostic cut-offs, diagnosis of hyperhidrosis is generally based on the history and examination of the individual, sometimes coupled with the use of one or more methods of quantification that can be objective or subjective.

Several objective methods of quantification exist, which tend to be used in research rather than in the clinical setting. One of the most common is gravimetry, which involves weighing the amount of sweat produced over a specific time period, typically through the use of filter paper that is in contact with skin. The surface area that produces sweat can also be visualized; for example, through starch-iodine or ninhydrin testing [9,10]. Additionally, the rate of water loss from the skin surface can be measured through the use of an evaporimeter [11].

Subjective methods of quantification allow a measure of the impact that the hyperhidrosis has on the individual. The dermatology life quality index has been used to assess hyperhidrosis, as have hyperhidrosis-specific questionnaires such as the hyperhidrosis

disease severity scale (HDSS) and the hyperhidrosis impact questionnaire (HHIQ) [3,12,13].

No single method is ideal, but coupled with the thorough assessment of the individual, the above methods of quantification can provide helpful information.

### Aims of treatment

The aim of treatment is to reduce the amount of sweating and to produce patient satisfaction.

### Relevant outcomes

Relevant outcome measures for the success of treatment are patient satisfaction and reduction in sweating as measured objectively and/or subjectively.

### Methods of search

Central, Medline, Embase, and Liliacs were searched for relevant articles. The last search for databases (see Appendix 59A) was June 2012. Additional supplementary searches were conducted in Central and PubMed in September 2012.

## Questions

### Which interventions reduce sweating effectively in patients with axillary hyperhidrosis?

#### Case scenario 59.1

A 24-year-old female patient presents to the outpatient department with excessive axillary sweating since her early teens. She has to change her clothes several times each day. Her clothes are heavily sweat stained around both axillae.

#### Aluminum chloride

Topically applied aluminum salts are some of the commonest treatments for hyperhidrosis. It has been suggested that long-term application leads to structural changes in the eccrine sweat glands and ducts, although the mode of action remains debated [14].

#### Benefits

There are no randomized controlled trials (RCTs), but there are some published case series. In a study by Scholes *et al.*, 65 patients were treated with 20% aluminum chloride hexahydrate in absolute alcohol, applied under occlusion nightly to dry axillae for seven nights and as required thereafter. Nearly all participants (64/65) achieved “complete control” of their hyperhidrosis at 12-month follow-up [15].

In a study by Brandrup and Larsen, 23 females with axillary hyperhidrosis were treated with 25% aluminum chloride solution with ( $n = 11$ ) and without ( $n = 12$ ) occlusion. Sweating was reduced by 60–80% both at rest and during exercise in both groups as measured by gravimetry [16]. Graber reported comparably successful treatment of axillary hyperhidrosis when using a 30% aluminum chloride solution ( $n = 10$ ) [17].

#### Harms

No serious adverse effects were reported with aluminum chloride. Skin irritation was reported by almost half of patients in the study by Scholes *et al.* when using the alcohol-based aluminum chloride solution, which in most cases was relieved by the topical application of 1% hydrocortisone [15]. In the study by Brandrup and Larsen,

itching was reported by all 23 patients, leading to discontinuation of treatment in two individuals. Occlusion was not tolerated by any patient [16].

#### Comments/implications for clinical practice

Despite the absence of good RCTs, 10–30% topical aluminum chloride is likely to be effective. It is often first-line treatment in axillary hyperhidrosis as it is readily available and relatively easy to use. There is a trade-off between adverse effects (commonly local skin irritation) and efficacy.

#### Botulinum toxin A

Botulinum toxin type A (BTX-A) is a bacterial toxin that can be injected into the deeper parts of the skin where the eccrine glands are located. It blocks acetylcholine release from cholinergic presynaptic vesicles, thus leading to chemodenervation of the eccrine glands and subsequently reduced sweat production [18]. Several brands of BTX-A are now available, including Botox® (or onabotulinumtoxinA) and Dysport® (or abobotulinumtoxinA) [19].

#### Benefits

There are no good systematic reviews available, though there are several RCTs. One large double-blind RCT by Lowe *et al.* ( $n = 322$ ) compared BTX-A (Botox) 75 U/axilla, 50 U/axilla and placebo over 1 year; 75% of BTX-A treated patients showed a greater than two-point improvement in the four-point HDSS questionnaire, versus 25% in the placebo group [20]. Median effect duration was 182 days, 159 days, and 62 days for the 75 U, 50 U, and placebo groups respectively. No significant difference was observed between the 75 U and 50 U groups in terms of HDSS improvement or duration of treatment effect.

In another RCT, 50 U of BTX-A (Botox) was used, where a  $\geq 50\%$  reduction in axillary sweating was found in 95% versus 32% of patients in the treatment and placebo groups respectively at week 1, and 82% and 21% at week 16 post BTX-A injection [21]. Longer term follow-up of a small proportion of subjects ( $n = 12$ ) from the same cohort over 18 months suggested the effect of BTX-A injections does not diminish significantly with repeated injections, although the duration of remission following injection was variable [22].

Another RCT evaluated 50 U BTX-A (Botox) in 207 subjects over 16 months. Response rates (as defined by a reduction of 50% as assessed by gravimetry 4 weeks post-treatment) were 96.1%, 91.1%, and 83.3% after the first, second, and third injections respectively. After the second injection, the mean duration of response was 30.6 weeks, with no anti-drug antibodies detected [23].

Heckmann and Plewig investigated the effect of 100–200 U BTX-A (Dysport) in 145 subjects in a double-blind RCT where each patient acted as their own control. At 2 weeks, a 50% reduction in sweating was achieved in 92.4% of patients receiving 200 U, 89% with the 100 U group, and 15.2% with placebo [24]. There was no statistically significant difference between 200 U or 100 U. A smaller ( $n = 43$ ) randomized unblinded study similarly found no significant difference in terms of efficacy between 100 U and 200 U Dysport [25].

#### Harms

There is no good evidence for systemic side effects: 5% of patients in one BTX-A trial reported increased sweating at non-treated sites post-injection (compensatory hyperhidrosis (CH)), versus none in

the placebo group [21]. In another study, 4.3% of patients reported CH [23].

Lowe *et al.* reported only pain as an adverse effect of axillary BTX-A injection, occurring in between 8 and 12% of patients depending on the study group (including placebo). The mean duration of pain was 2.4 days post injection [20]. One double-blind RCT compares BTX-A (Botox) reconstituted in lidocaine versus saline placebo ( $n = 29$ ) and found reduced pain scores for the axillae where lidocaine was used [26]. A double-blind placebo-controlled RCT evaluated topical tetracaine versus placebo before BTX-A (Dysport) injections, in which all patients reported less pain in the tetracaine pretreated axillae [27]. Another randomized study ( $n = 31$ ) further demonstrated reduced pain scores during BTX-A injections where the axillae is cooled for 1 minute pre-injection as compared with no cooling [28].

There is a theoretical risk of anti-BTX-A antibody formation, but this appears not to be an issue over 52 weeks in the studies by Lowe *et al.* [20] or Naumann *et al.* [23].

#### Comments/implications for clinical practice

Botox 50 U or Dysport 100 U per axilla appears to be effective in treating axillary hyperhidrosis. Pain on injection is common. BTX-A injections may be repeated as the patients relapse, but the intervals need to be adapted to the response of that individual.

### Oral anticholinergics

#### Benefits

Oral anticholinergics act on the same cholinergic fibers innervating eccrine glands that are blocked by BTX-A. There are no systematic reviews on their use in axillary hyperhidrosis. One small RCT ( $n = 41$ ) evaluating oral 50 mg methanthelinium bromide (Vagantin®) demonstrated a sweat rate reduction after 4 weeks as assessed by gravimetry: from  $89.2 \pm 73.4$  mg/min to  $53.3 \pm 48.7$  mg/min [29]. A double-blind RCT ( $n = 50$ ) compared the anticholinergic agent oxybutynin (dose increased incrementally up to 5 mg twice daily) with placebo in subjects with axillary or plantar hyperhidrosis and reported an improvement both in terms of level of sweating and in quality of life [30].

#### Harms

In the above oxybutynin study, 34.8% of subjects reported moderate–severe dryness of the mouth at 6 weeks [30]. Dry mouth was also the most commonly reported adverse effect in the study of methanthelinium bromide [29].

#### Comments/implications for clinical practice

At present, more evidence on safety/efficacy from larger trials is needed before reliable recommendations of anticholinergic agents can be made in the treatment of axillary hyperhidrosis.

### Iontophoresis

#### Benefits

There are no good RCTs on the use of iontophoresis for the treatment of axillary hyperhidrosis. Akins *et al.* evaluated the effect of a direct-current device for the treatment of hyperhidrosis [31]. Axillae of eight subjects were treated, with the contralateral axilla acting as a control. A 50% reduction in sweating was observed in three of eight axillae after 2 weeks of treatment as assessed through starch–iodine testing.

#### Harms

Akins *et al.* reported cases of skin discomfort during application of current and more rarely vesicle formation and scalding following treatment [31].

#### Comments/implications for clinical practice

There is at present little evidence that tap-water iontophoresis works in axillary hyperhidrosis. Anatomical factors mean application of current at this site might be less practical when compared with, for example, palms and soles.

### Destructive treatment strategies

Several surgical strategies exist for treating axillary hyperhidrosis, although they are not as widely used as the above treatment modalities. The principle is to remove or induce damage to the eccrine sweat glands.

#### Benefits

Rompel and Scholz compared subcutaneous curettage ( $n = 90$ ) with BTX-A (100 U Botox) injections in patients with axillary hyperhidrosis ( $n = 23$ ) [32]. The two treatments were comparable in terms of patient satisfaction: 66.3% of patient undergoing curettage and 60.8% of subjects receiving BTX-A reported the treatment as “good” or “very good” at the end of the observation period (28.2 months and 16.1 months for each respective treatment). A case-series of 28 patients undergoing axillary curettage by Darabaneanu *et al.* found a 70% reduction of sweating (as assessed by gravimetry) at 1 month and 58% at 1 year post-treatment [33]; 60.7% of subjects found the treatment “satisfactory,” “good,” or “excellent.”

Hasche *et al.* performed liposuction of the axillae in a series of 20 patients where 18 patients reported the outcome as “good” and one as “very good” 2–3 months post-treatment [34].

Glaser *et al.* evaluated a proprietary microwave device that induces thermal damage to eccrine glands ( $n = 120$ ) [35]. No significant difference was observed between treatment and placebo in the proportion of patients achieving a 50% reduction in sweating. However, there was a significant difference between patients achieving an improvement in HDSS score of 1 or 2 at 6-month follow-up (67% and 44% of subjects in the treatment and placebo groups respectively).

Bechara *et al.* hypothesized that treatment with an 800 nm diode laser might reduce axillary hyperhidrosis through disruption of sweat glands [36]. However, no difference was found between laser and sham treatment ( $n = 25$ ) [36].

#### Harms

Complications, such as infection, partial epidermal necrosis, and hematoma formation, were reported in 17.8% of patients who had subcutaneous curettage in the study by Rompel and Scholz [32]. Pain and hematoma formation were reported in the study evaluating axillary liposuction [34]. The most commonly reported adverse event in the microwave device study was altered sensation (9.9% of treated subjects), which resolved in all cases [35].

#### Comments/implications for clinical practice

There is insufficient evidence to support axillary curettage, liposuction, microwave devices, or laser therapy in the treatment of axillary hyperhidrosis. Side effects are potentially serious.

### Sympathectomy

Video-assisted thoracoscopic sympathectomy (VATS) involves disruption of the sympathetic innervation to the thoracic sympathetic

chain supplying the upper limbs and/or face. It is performed under general anesthetic.

### Benefits

In one study by Munia *et al.*, patients ( $n = 62$ ) were randomized to undergo denervation of T3–T4 or T4. At 6 months, 28/32 of those in the T3–T4 groups and 29/30 in the T4 group were “completely satisfied” with the outcome [37].

A retrospective study by Herbst *et al.* of 270 patients having undergone T1–T4 sympathectomies includes 39 patients with axillary hyperhidrosis [38]. Some degree of immediate improvement postoperatively was reported by 77%. Long-term satisfaction (follow-up 9 months–27.1 years) was significantly lower in subjects with axillary hyperhidrosis (33% “satisfied,” 46% “partially satisfied”) compared with patients with hyperhidrosis elsewhere.

### Harms

CH was reported by all subjects undergoing a T3–T4 sympathectomy, whilst the equivalent number was 43.3% in the T4 group [39]. Herbst *et al.* found that the main reason for being dissatisfied was postoperative CH/gustatory sweating, dry hands, and Horner’s syndrome. Overall, 67.4% patients reported CH, 50.7% gustatory sweating, and 2.5% Horner’s syndrome [38].

### Comments/implications for clinical practice

There is insufficient evidence to support sympathectomy for axillary hyperhidrosis. Data available suggest adverse effects such as CH and gustatory sweating are relatively common, though prospective long-term studies are needed.

## Which interventions reduce sweating effectively in patients with palmar hyperhidrosis?

### Case scenario 59.2

A 22-year-old male electrician complains of severe palmar sweating that interferes with his work. Palms are visibly wet at rest.

### Topical agents

#### Benefits

A double-blind RCT of 26 patients with palmar and/or plantar hyperhidrosis demonstrated an improvement in 24/26 patients after topical treatment with 5% methenamine (a formaldehyde-releasing compound, that possibly acts through causing blockage of sweat ducts). Results were generally less favorable for palms than for soles [40].

A further double-blind RCT ( $n = 109$ ) compared 5% methenamine with placebo for palmar and plantar hyperhidrosis. Using a 0–4 graded scale (0 being mildest), there was a significant improvement in sweating (palmar and plantar results pooled) with methenamine (3.2 at baseline, 1.4 post-treatment) compared with placebo (3.2 at baseline and 2.5 post-treatment). Of the patients in the treatment group, 71% rated it as “good” or “excellent” (vs 19% for placebo) [41].

A higher concentration of methenamine was used in a study by Phadke *et al.* that compared 10% methenamine, 5% glutaraldehyde, and tap water iontophoresis. “Good” or “excellent” results were reported by 19/20 of those treated with methenamine, 13/20 treated with glutaraldehyde, and 11/20 treated with iontophoresis after 4 weeks [42].

One study compared topical 20% tannic acid with iontophoresis for palmar hyperhidrosis but found no improvement with the former [43].

Goh compared topical aluminum chloride 20% in an alcoholic base with placebo in a single-blinded fashion ( $n = 12$ ), with each patient acting as their own control. Mean sweating decreased from 79.9 g/(m<sup>2</sup>h) water to 51.4 g/(m<sup>2</sup>h) water, whilst the equivalent figures for the placebo side were 77.9 g/(m<sup>2</sup>h) and 77.7 g/(m<sup>2</sup>h) water [44].

### Harms

No adverse effects were reported with methenamine in the study by Bergstresser and Quero [41]. Pigmentation and scaling were reported with methenamine and pigmentation alone with glutaraldehyde in the study by Phadke *et al.* [42]. All of 12 patients treating palms with 20% aluminum chloride reported dryness of the skin and 4/12 reported stinging [44].

### Comments/implications for clinical practice

There is insufficient evidence to recommend topical treatments for palmar hyperhidrosis, and further RCTs are required. There is limited evidence of benefit from topical 5% methenamine.

## Botulinum toxin A

### Benefits

There are three trials that evaluated BTX-A for palmar hyperhidrosis [45–47]. In a double-blind RCT, 19 subjects were treated with 100 U BTX-A (Botox) to each palm, with each patient acting as their own control [47]. All patients reported that the treatment was successful compared with 12% for placebo at 29-day follow-up.

Saadia *et al.* compared 50 U versus 100 U BTX-A (Botox) to each palm of 24 subjects, where 12 were nonrandomized and 12 randomized to the different treatment groups [46]. The percentage of the palmar surface that was sweating changed from  $76 \pm 19\%$  in the 50 U group and  $59 \pm 34\%$  in the 100 U group to  $22 \pm 29\%$  and  $11 \pm 14\%$  respectively within 1 month post-injection. The effect remained significant at 6 months in the 50 U group and 5 months in the 100 U group.

In a small double-blind RCT, 120 U BTX-A (Dysport) was injected into one palm of 11 patients, with saline injected into the contralateral palm. Sweating was reduced by 31% as assessed through ninhydrin testing (95% confidence interval, 20–40%) at 13 weeks in the BTX-A treated palm, with no statistically significant reduction in the placebo palm. Subjective patient-reported outcomes paralleled these results.

A small ( $n = 8$ ) RCT used a conversion factor of 1:4 to compare the efficacy of Botox and Dysport and found comparable results. They reported a 72% and 75% subjective reduction in sweating at 3 months and a mean duration of effect of 18 weeks and 17 weeks with Botox and Dysport respectively (range 8–32 weeks for either preparation) [48]. In contrast, a non-blinded study ( $n = 36$ ) concluded that the conversion factor between Dysport and Botox was closer to 1–1.5:1 [49].

There is further evidence of efficacy in treating palmar hyperhidrosis from case series for both Botox 50 U ( $n = 23$ ) and 230 U Dysport ( $n = 21$ ) [50,51]. Anhidrosis lasted 7 months (mean) with Botox and 11 weeks (median) with Dysport.

### Harms

BTX-A injections into the palms are painful, necessitating local or regional anesthesia [47,52]. Seventy-seven percent of patients in the 100 U BTX-A (Botox) group and 45% of patients receiving 50 U BTX-A reported hand/finger weakness. Subjective weakness lasted up to 22 days, but objective weakness (as assessed by a

dynamometer) persisted until 6-month follow-up. Four of 19 patients reported adverse effects with 100 U Botox in the study by Lowe *et al.*, including thumb/finger weakness, tingling/numbness, and pain [47]. Three of 11 reported hand weakness lasting 2–5 weeks following Dysport injections [45]. Weakness of hand muscles was also reported in the study by Schnider *et al.* [51]. There were no reports of CH.

### Comments/implications for clinical practice

Based on relatively small studies, BTX-A appears effective in treating palmar hyperhidrosis. Injections are painful and local or regional anesthesia is required. There is considerable heterogeneity in studies in terms of doses, duration of follow-up, and the number of injection sites used. Transient weakness appears to be the commonest adverse event. There is at present insufficient evidence to recommend any one BTX-A preparation.

## Oral anticholinergics

### Benefits

Evidence for anticholinergic drugs is based on case series only. In a study by Castells Rodellas *et al.*, 6/12 patients with palmar or plantar hyperhidrosis responded to bornaprine after 1 week [53]. Methentelium bromide was found to reduce sweating by 24–80% in a small study of four patients [54]. In contrast, one RCT found no benefit with methentelium bromide compared with placebo [29].

### Harms

Oral anticholinergics can be associated with systemic adverse effects (e.g., dizziness, dry mouth, and eyes). One of 10 patients in the case series by Castells Rodellas *et al.* had to stop bornaprine due to anticholinergic adverse effects [53].

### Comments/implications for clinical practice

There is at present no good evidence to support the use of oral anticholinergics in treating palmar hyperhidrosis.

## Iontophoresis

### Benefits

In an RCT by Stolman *et al.*, one hand was treated with iontophoresis with the other hand acting as a control. A reduction in sweating was noted in 15/18 subjects as assessed through gravimetry [55]. A small RCT treated one hand with iontophoresis and the other with placebo and demonstrated an 81% reduction in sweating in 6/11 subjects with repeated fortnightly treatment [56]. Phadke *et al.* reported “good” or “excellent” results in 11/20 subjects after 4 weeks of iontophoresis in a non-blinded RCT [42]. Aguilar-Ferrández *et al.* randomized 96 subjects to receive iontophoresis, relaxation exercises, or both. Gravimetry and starch–iodine testing showed a reduced level of sweating in those receiving iontophoresis or iontophoresis plus relaxation exercises (no numerical data provided), when compared with relaxation exercises alone. In both of these groups a significant reduction in anxiety scores was noted [57].

Akins *et al.* evaluated the effects of a portable iontophoresis device suitable for home use in 10 patients with palmar hyperhidrosis [31]. The mean area of sweating in the treated palm reduced from 9.71 to 2.26 square inches, whilst there was no significant change in the control palm. Hölzle and Alberti reported a reduction of sweating in 7/12 subjects using the same iontophoresis device [58].

Na *et al.* reported that 9/10 patients were satisfied with a dry type of iontophoresis device. Notably, histology showed disruption of eccrine glands only in the treated palms [59].

Though direct current (DC) is most commonly used, Reinauer *et al.* compared DC with alternating current (AC) and AC with DC-offset (AC/DC) in 25 subjects with palmo-plantar hyperhidrosis who were blinded to the type of current administered [60]. DC as well as AC/DC normalized palmar sweating after 11 sessions, whilst AC yielded no improvement.

### Harms

Stolman *et al.* reported vesiculation, erythema, and a tingling sensation in a minority of patients. They reported no cases of CH [55]. Dahl and Glent-Madsen reported bullae forming in 1/11 subjects [56]. Reinauer *et al.* reported mild discomfort/skin irritation with DC iontophoresis, but not with AC/DC iontophoresis. Local irritation and occasional staining of the palms was reported by Na *et al.* with dry current application [59].

### Comments/implications for clinical practice

There is some evidence, albeit from small studies, that iontophoresis is effective for treating palmar hyperhidrosis. Skin irritation, discomfort, and vesiculation/blistering have been reported. Further studies will need to establish the optimal dose/type of current, treatment duration, and frequency.

## Iontophoresis in combination with other treatments

### Benefits

In addition to lone current application, iontophoresis has been combined with other treatments.

Shen *et al.* compared iontophoresis alone and in combination with 20% aluminum chloride and 0.01% glycopyrrolate ( $n = 8$ ) and reported superiority of the latter regime [61]. Dolianitis *et al.* reported that iontophoresis with 0.05% glycopyrrolate is associated with longer remission (median 11 days) when compared with iontophoresis alone (median 3 days) [62]. Shimizu *et al.* compared iontophoresis alone or in combination with oral oxybutynin 4 mg/day ( $n = 19$ ) in a nonblinded RCT, but reported no significant differences between groups.

Kavanagh and Shams reported a double-blind RCT of eight patients where BTX-A (Botox) was delivered successfully to the palms using iontophoresis. Mean improvement in the BTX-A treated palm was 66% as assessed through gravimetry, with no improvement in the placebo side [63].

### Harms

Shen *et al.* reported one subject with mouth dryness, whilst some patients noted peeling or vesiculation after treatment [61]. AC iontophoresis with/without oxybutynin was well tolerated [64]. In the study of glycopyrrolate iontophoresis the only reported adverse effect was dryness/soreness of the mouth or throat, which appeared more severe in some patients when both palms, rather than one, were treated with glycopyrrolate [62].

### Comments/implications for clinical practice

Very limited data suggest iontophoresis combined with BTX-A or with glycopyrrolate and/or aluminum chloride might be superior to iontophoresis alone. However, further studies are required before such combinations can be recommended in clinical practice.

## Sympathectomy

### Benefits

A retrospective survey of 270 patients (total of 480 T1–T4 sympathectomies) reported an improvement in 98% of patients [65]. A larger retrospective study of 734 sympathectomies in 406 patients reported anhidrosis in 92% in those undergoing conventional (open) sympathectomy and 97% of those undergoing VATS [66].

Baumgartner *et al.* compared sympathectomy of the second and third costal heads (R2/R3) in 121 patients with palmo-plantar hyperhidrosis [67]. Forty-five percent of those in the R2 group and 41% of those in the R3 group were “moderately” or “very” satisfied with results at 1 year.

Yazbek *et al.* compared T2 with T3 sympathectomies ( $n = 60$ ). All but one patient in the trial reported complete resolution of their hyperhidrosis at 1 month and 6 months postsurgery [68]. Those who responded to treatment ( $n = 59$ ) were followed-up for a mean period of 20 months (range 12–34 months). The improvement in hyperhidrosis appeared to be sustained during long-term follow-up [69].

Yang *et al.* randomized 163 to undergo either T3 or T4 sympathectomy and reported a resolution of palmar hyperhidrosis in all cases [70]. Ishy *et al.* also compared T3 versus T4 sympathectomies in an RCT of 40 subjects. Sympathectomy reduced sweating as assessed by epidermal water loss; from 120 to 30 g/(m<sup>2</sup>h) and from 118 to 37 g/(m<sup>2</sup>h) in the T3 and T4 groups respectively at 1 year [11]. There were no statistically significant differences between the T3 and T4 groups.

### Harms

Herbst *et al.* reported CH in 67%, gustatory sweating in 51%, Horner's syndrome in 3%, and pneumothorax in 2% of survey responders [65]. Neumayer *et al.* reported CH in 68% and 56% (difference not significant) and gustatory sweating in 50% and 33% of subjects undergoing conventional and video-assisted sympathectomies [66].

There were no statistically significant differences in the incidence of CH when R2 and R3 sympathectomies were compared. No other adverse effects were reported. Sympathectomy failed in 4.1% and 4.2% cases in the R2 and R3 groups respectively. The incidence of CH of any severity was 75.5% (R2) and 58% (R3), though the difference between R2 and R3 was not statistically significant [67].

CH was reported in all patients post T2 sympathectomy and in all but one patients post T3 sympathectomy at 6 months. There was one case of Horner's syndrome in 60 subjects [68]. Long-term follow-up suggests CH persisted for a mean period of 20 months [69]. CH occurred in significantly more subjects who underwent T3 compared with T4 sympathectomies in the study by Ishy *et al.*, in 20/20 versus 15/20 patients respectively [11]. Yang *et al.* report the same incidence of CH with T3 and T4 sympathectomies, but with a significantly larger number with more severe CH in the T3 group (mean follow-up 13.8 months) [70].

### Comments/implications for clinical practice

There is evidence for sympathectomies being effective for treating palmar hyperhidrosis. However, it is not clear which level is most effective and associated with fewest adverse effects. Retrospective data suggest comparable efficacy for conventional and video-assisted sympathectomies, but with a lower incidence of gustatory hyperhidrosis in the latter. Adverse events, in particular compensatory and gustatory sweating, are common and can be permanent. Sympathectomies should therefore not be considered a first line therapy.

### Key points

- Limited data suggest 10–30% aluminum chloride is effective, but there is a trade-off between efficacy and adverse effects (commonly skin irritation).
- RCT evidence suggests that botulinum toxin A is effective in focal hyperhidrosis. There are several commercial preparations available but it is unclear how they compare unit-per-unit in terms of efficacy, safety, and treatment duration. Adverse effects include pain on injection and compensatory hyperhidrosis (CH).
- There is limited evidence for the efficacy of oral anticholinergic drugs in axillary hyperhidrosis, but not for palmar hyperhidrosis. Their use is associated with anticholinergic adverse effects.
- Iontophoresis may be effective for palmar hyperhidrosis, though its efficacy in axillary hyperhidrosis is questionable. Local irritation is common.
- There is little evidence at present to support surgical removal of sweat glands, or the use of curettage, liposuction, microwave devices, or lasers in treating hyperhidrosis.
- There is evidence for efficacy of sympathectomy for palmar and to a lesser degree axillary hyperhidrosis. Adverse effects (notably CH and gustatory sweating) are common and may be permanent. For this reason, sympathectomies should only be considered in severe cases refractory to other treatments.

## Acknowledgments

We would like to thank the authors of the previous edition of this chapter: Hendrik Zielke, Thomas Sycha, and Peter Schnider. We are grateful to Elizabeth Doney and the Cochrane Skin Group (Nottingham, UK) for the search strategies.

The University of Manchester, Manchester Academic Health Science Centre, Manchester, UK; The Dermatology Centre, Salford Royal NHS Foundation Trust, Salford, UK

**Background**

Minimally invasive cosmetic procedures are increasingly popular treatments for rejuvenation. Dermal fillers are used to improve contours and wrinkles which occur as a result of volume loss and repetitive muscle contraction. A wide variety of fillers is available, ranging from temporary agents such as hyaluronic acid (HA), to permanent agents such as polyacrylamide hydrogel. Temporary fillers are often preferred owing to a more favorable side-effect profile. Furthermore, facial ageing is a dynamic process; therefore, use of temporary fillers allows for adjustment of treatments over time.

**Etiology**

Facial ageing is a complex process due to a combination of changes occurring at all tissue levels from the epidermis to the facial skeleton. Cutaneous ageing occurs as a result of extrinsic factors, primarily ultraviolet radiation, superimposed on chronologic or intrinsic skin ageing. The epidermis may be thinned, and an increase in the activity of proteolytic enzymes results in reduced collagen expression. Repeated exposure to ultraviolet radiation leads to deposition of abnormal elastotic material in the dermis. There is atrophy of subcutaneous tissues; the diminution and flattening of discrete facial fat pads with subsequent malposition results in phenotypic changes characteristic of the older face; for example, flattening of the mid face and jowl formation [1]. Dynamic lines and wrinkles associated with facial expression can with time become permanent creases present at rest. Changes in the facial skeleton including the orbital aperture and mandible may result in altered prominence of periorbital fat pads, deepening of sulci, and decreased chin projection [2,3].

**Aims of treatment**

The aim of treatment with dermal fillers is to replace volume to produce a more youthful appearance.

**Relevant outcomes**

The majority of studies are focused on treatment of nasolabial folds (NLFs) and assess improvements in the five-point wrinkle severity rating scale (WSRS, a scale of 1–5, where 1 indicates no visible fold

and 5 indicates extremely deep and long folds) and the global aesthetic improvement scale (GAIS, where the improvement is rated on a five-point scale: 0 indicates worse and 4 indicates very much improved) [4]. The duration of effect is also an important consideration.

**Methods of literature search**

The following databases were searched using the term “dermal filler” or “dermal fillers”: The Cochrane Library, PubMed, OVID, and the Clinical Trials Database. All randomized studies of dermal fillers used for the purposes of facial rejuvenation were included. Trials of dermal fillers for the treatment of HIV-associated lipodystrophy or skin diseases such as acne were excluded.

**Questions****Which fillers are effective in treatment of nasolabial folds?**

The vast majority of randomized studies have compared the effects of two or more different types of fillers in the treatment of NLFs. HA-based products are the most studied, with a number of trials demonstrating significant improvement in NLFs following treatment. Most studies received industry funding.

**Hyaluronic acid**

HA is a glycosaminoglycan found within the dermis. A number of HA-based formulations are available for rejuvenation. Nonanimal HA products are made from bacterial fermentation cultures. Several double-blind (subject and evaluator blind) studies have shown that some crosslinked HA fillers (e.g., Emervel Classic, Emervel Deep, Restylane, Restylane Perlane, Teosyal Deep) and to a lesser extent non-cross-linked HAs (Mesoglow, IAL-System) are effective in the treatment of NLFs, with the duration of treatment efficacy for cross-linked products generally assessed up to 6 months [5–9]. A single-blind randomized study of 77 individuals studied two different nonanimal stabilized HA (NASHA) products with different physicochemical qualities, including degree of cross-linking (Perlane and Juvederm ULTRA PLUS) over 12 months [10]. Although both

products resulted in similar improvements in WSRS up to 3 months posttreatment, at 6, 9, and 12 months the proportion of patients with clinically relevant improvement (one point difference in the WSRS) was greater in the Juvederm ULTRA PLUS treated side. The authors hypothesized that the greater degree of cross-linking and dense network of HA polymers increased the longevity of the product. A small randomized split-face study comparing three different HA fillers also reported benefits lasting up to the final 12-month follow-up [11].

The majority of patients studied have been Caucasian; however, one study has shown that NASHA gels are safe and effective in the treatment of NLFs in 150 individuals with Fitzpatrick skin types IV to VI, although pigmentary disturbance was reported in 6–9% of patients depending on the type of NASHA used [12]. A number of randomized controlled trials (RCTs) have compared NASHA filler containing lidocaine with the same product without lidocaine [13–16]. All revealed significantly lower reported pain scores with the lidocaine-containing product (varying from time of injection to 120 mins post injection), and the majority of patients preferred the lidocaine-containing products; efficacy and safety were not affected.

Nonanimal stabilized HA fillers have been compared with other HA products. A randomized study of 15 patients comparing NASHA (Restylane) with an avian-derived HA (Hylan B gel) in a split-face design showed that, although both products led to improvement in NLFs as assessed by physician- and patient-reported WSRS, the effects of NASHA were more pronounced and more long lived (improvement maintained at final 6-month assessment, compared with 3 months for avian-sourced HA) [17]. More recently, a randomized evaluator blinded study of 140 subjects reported equivalent safety and efficacy of a novel divinyl sulfone cross-linked HA (Prevelle lift) compared with NASHA (Restylane) in the treatment of NLFs [18].

### Drawbacks

Adverse events reported include bruising, redness, swelling, pain, itching, and nodules lasting several days [6,11,17,19]. In one study redness lasted beyond 2 weeks in an unspecified number of patients [16], whilst in a separate study of 248 subjects treated with NASHA, six developed masses or nodules, two of which required treatment [5].

Please note that in contrast to all other fillers, in case of overcorrection and adverse reactions to HAs an antidote (hyaluronidase) is available.

### Collagen

The most-studied collagen fillers are bovine in origin, although porcine and human collagen products are or have also been available. Owing to the immunogenicity of bovine collagen, patients must have hypersensitivity testing prior to filler injection. A split-face randomized trial of 137 patients treated with bovine collagen (Zyplast) and NASHA (Restylane) in NLFs reported significantly greater improvement in the WSRS and GAIS at 2, 4, and 6 months post injection in the NASHA-treated side (although both resulted in improvement compared with baseline). Delayed-onset reactions (mainly redness) occurred in 10 NASHA and 11 bovine collagen-treated sites, but none were considered hypersensitivity reactions and all resolved spontaneously [4]. Similar findings were reported in four subsequent randomized trials, again using split-face designs, to compare bovine collagen with different HA fillers (number of subjects ranging from 69 to 439) [20–23]. The effects of the HA fillers were longer lasting (up to 12 months), and adverse events

were similar (mainly short-lived injection-site reactions). In one of the studies the incidence of local injection-site reactions with bovine collagen was 30.9% compared with 17.6% with NASHA [22].

More recently, porcine collagen has been studied as an injectable filler. A small randomized split-face study of 12 patients injected with bovine collagen (Zyplast) and porcine collagen (Evolve) into NLFs found that, although both treatments improved NLFs, the effects of porcine collagen persisted for longer [24]. Comparison of porcine collagen (Evolve) with NASHA (Restylane) in an evaluator and subject blind RCT of 149 patients revealed that both treatments led to significant improvement in NLFs with no differences between the two fillers [25]. A follow-up study showed that at least some improvement (0.5-point improvement in a modified WSRS, ranging from 0 to 4) was still evident in the majority of patients (76.5%) treated with porcine collagen at 12 months [26]. Six months after injection of porcine collagen, local injection-site reactions (including induration) were present in 3.4% of subjects, compared with 0.7% with NASHA.

Please note that in most parts of the world collagens are not available anymore.

### Poly-L-lactic acid

Poly-L-lactic acid (PLLA) is a biodegradable polymer that has been shown to be effective in the correction of NLFs. A randomized evaluator blind study of 233 patients treated with either PLLA or human collagen to NLFs (up to four treatments given over 3-week intervals to achieve optimum correction, using a six-point WSRS) demonstrated a significant improvement in NLFs with both treatments. At 3-month follow-up no significant difference compared with baseline was apparent in the collagen group. In contrast, PLLA resulted in significant reduction in NLF severity score up to 25 months [27]. However, the correction was modest and less than that seen in HA filler studies. Injection-site reactions occurred more commonly in the collagen group, although a higher incidence of application-site papules was noted in the PLLA group.

Please note that the correction achieved with PLLA was less than for HAs and that, in contrast to the HAs, no antidote exists for overcorrection or in case of adverse events.

### Calcium hydroxylapatite

Calcium hydroxylapatite (CaHA) is a mineral complex that is used as a temporary dermal filler for facial rejuvenation. A randomized split-face evaluator blind study of CaHA (Radiesse) versus human collagen in the treatment of 117 patients showed that significantly more NLFs treated with CaHA had improved in terms of wrinkle severity scores at 3 months (87% improved compared with 27% of collagen treated) [28]. The same effect was observed at 6-month follow-up. Swelling and bruising were more common in the CaHA-treated side. Two randomized split-face studies comparing CaHA with HA products showed different results. The larger study did not show a difference in the WSRS, whereas the smaller study favored in the WSRS the CaHA-treated site [29,30]. Patient preference and satisfaction with treatment favored CaHA (however, one has to note that neither study was double blind; therefore, a bias might favor the treatment under study), and no serious adverse events were reported for either treatment. Two small randomized split-face studies have compared CaHA with and without lidocaine for the treatment of NLFs [31,32]. One double-blind study of 16 patients found an improvement in pain scores with no difference in efficacy up to 6 months posttreatment [31]. A second randomized study of

50 patients showed improvement in pain scores both at the time of injection and up to 1 h post injection. This study was limited by the lack of evaluator blinding and a short follow-up period of 1 month [32].

Please note that, in contrast to the HAs, no antidote exists for overcorrection or in case of adverse events.

### Autologous fibroblast therapy

A randomized placebo-controlled study of 372 patients has shown that autologous fibroblast therapy resulted in greater improvement in NLF wrinkles during the 6-month study period when compared with placebo injection, although there was a notable placebo effect [33]. Adverse events were generally injection related: redness occurred more commonly following fibroblast injection, whereas bruising occurred more commonly after placebo. Two individuals treated with fibroblast injections developed papules and a further two developed hyperpigmentation lasting beyond 2 weeks. Without an active comparator arm the results are difficult to interpret.

Please note that this is not a commonly used intervention.

### Polymethylmethacrylate microspheres and polyacrylamide hydrogel

Polymethylmethacrylate microspheres suspended in bovine collagen, known as Artecoll or Artefill, can be used as permanent injectable filler. One double-blind randomized study of 251 patients compared Artecoll with bovine collagen (Zyderm/Zyplast) in the treatment of glabellar lines, upper lip lines, NLFs, and marionette lines [34]. At 6-month follow-up the improvements in observer-rated facial fold severity scores across facial areas overall were significantly greater in the Artecoll group. The effects were persistent at 12-month follow-up, although data were only available for the Artecoll group. The numbers of adverse events were similar in both groups and were mainly injection-site reactions, although more patients in the Artecoll group had lumpiness lasting more than 1 month at the injection site (eight compared with four).

Injectable filler containing polyacrylamide hydrogel has been compared with NASHA in the treatment of NLFs in a randomized double-blind study of 315 patients [35]. The treatments were equivalent in terms of improvement in WSRS at 12 months. The majority of adverse events were injection-site reactions; more than 85% of which resolved in less than 7 days. One patient treated with polyacrylamide hydrogel developed an infection requiring antibiotics and filler removal. Further studies are required to assess the long-term safety of the filler.

There have been a number of reports of granulomatous reactions occurring months to years post injection of these permanent fillers (0.6% occurrence rate with polymethylmethacrylate microspheres). Treatments include intralesional steroid injection or surgical removal of the implant [36].

Please note that permanent fillers should always be scrutinized for long-term safety.

### Which fillers are effective in the treatment of glabellar lines?

One small randomized study of 38 female patients compared NASHA alone with NASHA and botulinum toxin in the treatment of moderate to severe glabellar lines [37]. A significantly higher proportion of subjects receiving the combined treatment achieved improvements in wrinkle scores from week 0 to week 32. The rates of adverse events were similar, although one patient in the NASHA

group developed what was presumed to be a delayed reaction to NASHA that responded to intralesional steroid injection.

### Which fillers are effective in cheek augmentation?

One RCT of 107 patients has studied the effect of CaHA in cheek augmentation [38]. Patients receiving treatment were compared with an untreated control group at 3 months. The untreated group then went on to have treatment at 3 months. The treated group had greater GAIS at 3 months, and 77.9% of patients were satisfied or extremely satisfied with the treatment. Injection-site reactions were common, with 6.5% of patients reporting lumps and 1.9% reporting nodules (duration not stated). Again, this trial is hampered by a missing active comparator.

### Which fillers are effective in lip augmentation and rejuvenation of the lower face?

A double-blind randomized comparison of porcine collagen, bovine collagen, or HA (Perlane) to treat wrinkles in the upper lip of 79 patients demonstrated modest increases in lip volume post injection [39]. Herpes zoster was the most common adverse event in all groups. Larger studies are necessary to determine the safety and efficacy of fillers in lip augmentation.

One RCT has reported the effect of HA with or without botulinum toxin for lower facial rejuvenation [40,41]. Ninety subjects were enrolled; although only 73 attended the 24-week follow-up. Subjects receiving combination treatment in general had greater improvements in investigator assessments with a longer duration of response. Adverse events were more noticeable in the botulinum-toxin-treated group.

HA has been shown to be effective in lip augmentation in a randomized evaluator-blind trial of 180 patients, although the comparison group had no treatment [42]. Injection-site reactions were mainly mild in severity and lasted 5–10 days after injection.

## Summary

In contrast to other interventions in esthetic medicine, at least some randomized clinical trials exist investigating a number of injectable fillers available in the marketplace. However, not every trial is a good one, and the common indications for use of such fillers now far outstrip the available randomized, blinded clinical evidence. The users should scrutinize the evidence carefully in several instances: (1) Small trials – results are more likely to be due to chance. (2) Single-blinded trials where one investigator is blinded; for example, the WSRS results may be reliable but subjective patient-centered results may be biased to the new treatment. (3) Trials with a weak comparator – bovine collagen was nearly always inferior to the new fillers investigated (one of the reasons they are no longer marketed in Europe and the USA); therefore, it is not surprising if a filler is superior to bovine collagen. (4) Trials with no comparator – a study with absence of a comparator might mean that the study designers are not sure of the effect of their product compared with a standard HA; for example, the effect may at best be equal to or even inferior to that of a standard HA. (5) Last but not least, permanent fillers. This is a specific group. Attention should be paid here not only to short-term safety, but also to long-term safety.

# Reducing mimic wrinkles and folds with botulinum toxin A

**Berthold Rzany**

RZANY & HUND, Privatpraxis für Dermatologie und Ästhetische Medizin, Berlin, Germany

## Background

Mimetic muscles create facial expressions. Because these are usually attached to the dermis, activation can result in development of temporary cutaneous wrinkles and folds which convey emotion. Over time and with repeated muscular activity, temporary lines and wrinkles in the skin may become permanent and persist at rest. Wrinkles and folds are significantly associated with aging [1]; therefore, modification of these will be inexorably linked with facial rejuvenation.

The most basic intervention to decrease mimetic wrinkles and folds is treatment with botulinum toxin type A (BoNT-A). BoNT-A binds uniquely at the acetylcholine-triggered neuromuscular synapse temporarily blocking muscular activity (de Maio and Rzany, 2007). There are several BoNT-A preparations on the market. This chapter will focus on the three brands available in Europe and North America (Table 61.1), although other preparations are available worldwide; for example, Neuronox [2].

## Aim of treatment

The aim of treatment is to decrease muscular activity and thus decrease the severity of wrinkles and folds.

## Outcome criteria

Efficacy of treatment is measured by clinical severity scales. These four- to six-point scales range from “no wrinkles” up to “extreme wrinkles.” The clinical scales can be used by physicians as well as patients. They have been used with life patients as well as photographs. In clinical trials, physicians and patients are usually blinded. If for some reason the treating physician cannot be blinded, then to increase the level of blinding a blinded evaluator can be used. Reproducibility of these scales has been shown to be good to excellent [3,4]. In most BoNT-A studies, a four-point score is used. Treatment success might be defined as either the proportion of patients with mild or no wrinkles or alternatively as at least a one point or two point difference in the wrinkle score. Treatment success of either outcome measurement is usually associated with high patient satisfaction despite which main objective outcome criterion was used [5]

## Relevant clinical questions

Since the early 1990s [6] BoNT-A has been used for a multitude of indications, mostly focusing on muscle-induced wrinkles and folds ranging from the glabella to the platysmal bands. Based on these different indications, as well as the desired wanted and unwanted outcomes, there are a multitude of possible questions. Some of these questions will focus on indications (e.g., the glabella, the forehead, crow’s feet), mode of treatment (e.g., distribution of injection points, dilution used), as well as general aims of treatment. Here, we can only provide a brief overview, focusing on four relevant clinical questions:

- 1 What is the optimal dosage for the muscles (m. corrugatores, m. procerus) inducing vertical and/or horizontal wrinkles/folds of the glabella?
- 2 What is the optimal dosage for the muscle (m. frontalis) inducing horizontal wrinkles/folds of the forehead?
- 3 What is the evidence for reducing injection pain when administering BoNT-A?
- 4 What is the evidence that BoNT-A may be used for the prevention of wrinkles and folds?

## Methods

Criteria for inclusion were unsystematic searches in the Cochrane library as well as Embase and Medline, with a focus on systematic reviews and randomized controlled clinical trials (RCTs) up to December 2012. Search terms were botulinum toxin, the drug names,<sup>1</sup> glabella, forehead, crow’s feet, pain, preserved saline, as well as clinical trial and randomised/randomized. Small RCTs and RCTs with inappropriate study designs were excluded. Good examples of inappropriate study designs are the studies from Prager and Rappl. [7] and Moers-Carpi *et al.* [8], where two dosages in two

<sup>1</sup>The different toxin preparations can be found under different names in the data banks, ranging from their trade names to designed names that are preferred by the US Food and Drug Administration (FDA). For example, Botox (original trade name, used for medical as well as esthetic indications – sometimes with the addition of “cosmetic” – is also called Vistabel/Vistabex/Vista (trade name for esthetic indications in some countries) as well as onabotulinumtoxin (the designed name preferred by the FDA) (see also Table 61.1).

different products were compared in a two arm study. An appropriate study design would have required here a four-arm study. Excluded were also a couple of forehead studies as they focused more on the comparison of different BoNT-A preparations than on the optimal dosage for this indication [9,10].

## Clinical questions

### What is the evidence for the optimal dosage for treating vertical and/or horizontal wrinkles and folds of the glabella?

Glabella wrinkles and folds are induced basically by two muscle groups: the procerus (leading to horizontal lines) and the corrugators (leading to vertical lines). In clinical trials, usually five to seven injection points are delivered.

### Randomized controlled trials and meta-analyses

There is one company-sponsored meta-analysis available [11]. In addition, several good controlled trials can be found. The trials will be discussed for each brand separately.

**Table 61.1** Botulinum toxin A preparations available in Europe and the USA.

Trade name	Units <sup>a</sup> per vial	US acronym	Company
Azzalure <sup>b</sup> /Dysport	125 <sup>b</sup> /300 or 500	AbobotulinumtoxinA (Abo-BoNT-A)	IPSEN
Bocouture/Xeomin	50/100	IncobotulinumtoxinA (Inco-BoNT-A)	Merz
Vistabel, Vistabex, Vista/Botox	50/100	OnabotulinumtoxinA (Ona-BoNT-A)	Allergan

<sup>a</sup>1 U of Azzalure/Dysport is approximately equivalent to 2.5 U of Vistabel/Botox. 1 U of Bocouture/Xeomin is approximately equivalent to 1 U of Vistabel/Botox.

<sup>b</sup>Distributed by Galderma.

### Ona-BoNT-A (Botox or Botox Cosmetic or, for example, Vistabel)

There are several trials focusing on the optimal dosage for Ona-BoNT-A in the glabella area (Tables 61.2 and 61.3).

**Five injection-point studies** The standard dose used is 20 U Ona-BoNT-A distributed in five injection points. In the first large placebo-controlled trial, patients with moderate to severe glabellar lines at maximum frown received intramuscular injections of 20 U Ona-BoNT-A or placebo into five glabellar sites. A total of 264 patients were enrolled (203 treated with Ona-BoNT-A, 61 with placebo). There was a significantly greater reduction in glabellar line severity with Ona-BoNT-A than with placebo (all measures, every follow-up visit;  $P < 0.02$ ). The effect was maintained for many patients throughout 120 days, the duration of the study [12]. Similar studies were conducted in Asia [13,14]. The Japanese study was a three-arm study additionally investigating an 10 U Ona-BoNT-A arm [13]. Study designs and results were comparable; therefore, the meta-analysis was performed focusing on the duration of the effect (Table 61.2).

**Seven injection-point studies** The same authors investigated in a double-blind, randomized clinical trial the efficacy, safety, and duration of the effect of four different doses of Ona-BoNT type A in the treatment of glabellar rhytids in females. Eighty female subjects with moderate to severe wrinkles at maximum frown entered the study. Patients were randomly administered 10, 20, 30, or 40 U Ona-BoNT-A in seven injection points. Objectively, 10 U of Ona-BoNT type A was significantly less effective than 20, 30, or 40 U. The relapse rate at 4 months was significantly higher in the 10 U group (83%) versus 40, 30, or 20 U (28%, 30%, and 33% respectively). The authors concluded that 20–40 U Ona-BoNT-A were significantly more effective at reducing glabellar lines than 10 U [15].

**Table 61.2** RCTs focusing on the BoNT-A dosage (here the Botox family of products) for the glabella using five injection points.

Author Year Country	Study type No. of patients % female Dose Injection points	Outcome criteria	Results	Comment
Carruthers <i>et al.</i> [12] 2002 USA and Canada	RCT 203 Ona-BoNTA and 61 placebo 85.2% and 77% respectively 20U or placebo 5	Physician assessment Responder: grade 0 or 1 at maximum frown	At day 30: placebo, 1.6%; 20U Botox, 83.7%	
Carruthers <i>et al.</i> [17] <sup>a</sup> 2003 USA and Canada	RCT 202 Ona-BoNTA and 71 placebo 79.7% and 83.1% respectively 20U or placebo 5	Physician assessment Responder: grade 0 or 1 at maximum frown	At day 30: placebo, 7%; 20U Botox, 76.7%	Placebo rate estimated from graph may be a bit lower
Wu <i>et al.</i> [14] <sup>a</sup> 2010 China	RCT 170 Ona-BoNTA and 57 placebo 85.9% 20U or placebo 5	Physician assessment Responder: grade 0 or 1 at maximum frown	At day 30: 20U Botox 94.1%; placebo, 3.5%	
Harii and Kawashima [13] <sup>a</sup> 2008 Japan	RCT 142 patients 90% 10 or 20U Ona-BoNT-A or placebo 5	Physician assessment Responder: grade 0 or 1 at maximum frown	At 4 weeks: 10U Botox 86.4%; 20U Botox 88.6%; placebo 0%	Both doses are efficient

<sup>a</sup>Evaluated in a meta-analysis.

**Table 61.3** RCTs focusing on the BoNT-A dosage (here the Botox family of products) for the glabella using seven injection points.

Author Year Country	Study type No. of patients % female Dose Injection points	Outcome criteria	Results	Comment
Carruthers and Carruthers [16] <sup>a</sup> 2005 Canada	RCT 80 Ona-BoNT-A 0% 20, 40, 60, or 80 U Ona-BoNTA 7	Physician assessment Responder: grade 0 or 1 at maximum frown	At 1 month: 20 U Botox, 65%; 40 U Botox, 90 %; 60 U Botox, 95%; 80 U Botox, 100%	All-male study
Carruthers <i>et al.</i> [15] 2005 Canada	RCT 80 Ona-BoNT-A 100% 10, 20, 30, or 40 U Ona-BoNTA 7	Physician assessment Responder: grade 0 or 1 at maximum frown	At 4 weeks: 10 U Botox, 68%; 20 U Botox, 78%; 30 U Botox, 98%; 40 U Botox, 100%	All-female study 10, 20, and 30

<sup>a</sup>Estimated from the graphs.

A similar study in male patients was published the same year. In this comparable study, 80 men were randomized to receive a total dose of either 20, 40, 60, or 80 U of Ona-BoNT-A distributed in seven points in the glabella and lower forehead area. The 40, 60, and 80 U doses of Ona-BoNT type A were consistently more effective in reducing glabellar lines than the 20 U dosage (duration, peak response rate, improvement from baseline). There was a dose-dependent increase in both the response rate at maximum frown and the duration of effect assessed by the trained observer. The authors concluded that male participants with glabellar rhytids benefit from starting doses of at least 40 U of Ona-BoNT-A [16] (Table 61.3). With seven injection points the recommended dosages are higher than for the five injection point studies.

#### **Abo-BoNT-A (Dysport or Azzalure)**

Up to now there has been no meta-analysis published. However, there is a clinical overview which summarizes the relevant clinical data for Abo-BoNT-A [5]. In this overview there are a total of 11 clinical studies evaluated, the majority being RCTs. For this review we focus on RCTs only.

So far there are four more-or-less comparable trials published focusing on the optimal dosage for the glabella [18–21]. The baseline is a dose ranging study from Ascher *et al.* [18] comparing 25, 50, and 75 sU Abo-BoNT-A compared with placebo. A total of 119 patients with moderate to severe glabellar lines at rest were treated. The dose was distributed over five intramuscular glabellar sites forming a bird-shaped pattern. Outcome measures included evaluations of glabellar lines by independent experts from blinded standardized photographs at rest 1 month after treatment, physician evaluations, and patient assessments during a 6-month period. A significant efficacy was reported for the three Abo-BoNT-A groups for at least 3 months after injection (at least  $P < 0.015$ ). Investigator and patient evaluations suggested that 50 sU was the optimal dosage [18]. These results are supported by the US study from Monheit *et al.* [19] and Brandt *et al.* [21].

The most interesting study is that from Kane *et al.* [22] looking at variable dosages. In this study Abo-BoNT-A was administered in a total volume of 0.4–0.6 mL for women (50, 60, or 70 sU) and 0.5–0.7 mL for men (60, 70, or 80 sU), based on procerus/corrugator muscle mass (e.g., the activity of the muscles). At day 30, 85% and 87% of Abo-BoNT-A-treated patients were responders as assessed by blinded evaluator and patient self-evaluation, respectively, compared with 3% and 5% of placebo-treated patients, respectively

( $P < 0.001$ ). This study shows that an individualized treatment will lead to an increased efficacy (Table 61.4).

#### **Inco-BoNT-A (Xeomin or Bocouture)**

For Inco-BoNT-A (Xeomin) no placebo-controlled studies have been published so far. There is only one study that does not see a difference between 24 U of Inco-BoNT-A (Xeomin) and Ona-BoNT-A (Botox) for the glabella (Table 61.5).

#### **Summary**

Based on these studies (with an overwhelming female study population) 20 U Ona-BoNT-A (Botox) and 50 sU Abo-BoNT-A (Dysport) seems to be the optimal dosage when treating the glabella only. This corresponds to a 1:2.5 ratio between both products, taken on the existing data alone. When treating the glabella and forehead with two additional points the optimal dosage seems to be higher. Using a seven-point injection scheme Carruthers and Carruthers [16] suggested 40 U Botox to be the optimal dosage for the treatment in men.

For Inco-BoNT-A (Xeomin) no placebo-controlled studies have been published so far. Therefore it can only be assumed that the optimal dosage corresponds to the dosage of Ona-BoNT-A.

It is useful to note that the studies discussed here may comprise quite different patient populations; therefore, simple informal indirect comparison between the efficacy rates of the different products may be misleading. A real comparison would require a head-to-head trial.

Another confounding issue is the paucity of data for the esthetic use of BoNT-A in areas other than the glabella. The reluctance of regulatory agencies to accept clinical studies outside their jurisdiction is certainly a contributory factor. There would be significant clinical benefit for utilization of resource on other important applications of BoNT-A; for example, crow's feet and forehead wrinkles.

#### **What is the evidence for the optimal dosage for treating horizontal wrinkles and folds of the forehead?**

Besides the glabella, the wrinkles and folds of the forehead are the most frequently treated indications. These mostly horizontal wrinkles and folds are induced by one major muscle: the frontalis. This is the only elevator for the upper third of the face; therefore, over-treatment will inevitably lead to brow ptosis, which is associated

**Table 61.4** RCTs focusing on the BoNT-A dosage (here the Dysport/Azzalure product family) for the glabella. The dosage is given in Speywood units (sU).

Author Year Country	Study type No. of patients % female Dose Injection points	Outcome criteria	Results	Comment
Ascher <i>et al.</i> [18] 2004 France	RCT 119 95.8% 25–75 sU 5	Assessment at rest	44.8% in the BonNT-A (25 sU) and BonNT-A (50 sU) groups ( $P = 0.015$ ); 55.2% in the BTX-A (75 sU) group ( $P = 0.005$ ); and 6.7% in the placebo group	Assessment was done at rest. This makes the study difficult to compare
Rzany <i>et al.</i> [20] 2006 Germany	RCT 110 and 111 89.9% and 90.1% 30–50 sU 3 or 5 (the latter distributed in a U-shape pattern)	Assessment by experts based on photographs Responder: a reduction of at least 1 point between weeks 0 and 4	After 4 weeks, the proportions of responders were 86.1% vs 18.9% for 30 sU and 86.3% vs 7.9% for 50 sU	This was not a dose-finding study. Two different injection point distributions and dosages were compared with placebo
Monheit <i>et al.</i> [19] 2007 USA	RCT 373 83.9% 20–75 sU 5	Physician assessment Responder: grade 0 or 1 at maximum frown	At day 30: Placebo, 9%? 20 sU, 68%? 50 sU, 79%? 75 sU, 84%?	Data not given in paper, the proportions are estimated from a PP from Gary Monheit. 50 sU Dysport were determined to be the optimal dosage
Brandt <i>et al.</i> [21] 2009 USA	RCT 158 85% 50 sU 5	Physician assessment Responder: grade 0 or 1 at maximum frown	At day 30: 50 sU, 89%; placebo, 3.9%	
Kane <i>et al.</i> [22] 2009 USA	RCT 816 88% Variable dose (50, 60, or 70 sU) for women and (60, 70, or 80 sU) for men 5	Physician assessment Responder: grade 0 or 1 at maximum frown	At day 30: variable dosages sU 85% Placebo: 3% Median duration of effect: 109 days (blinded evaluator) vs 0 days for placebo	Very innovative study trying to individualize dosages based on muscle mass

**Table 61.5** RCTs focusing on the BoNT-A dosage (here the Xeomin/Bocouture product family) for the glabella.

Author Year Country	Study type No. of patients % female Dosage Injection points	Outcome criteria	Results	Comment
Sattler <i>et al.</i> [23] 2010 Germany, Austria, UK	RCT 381 Inco- or Ona-BoNT-A patients 100% 24U 5	Physician assessment Responder: 1 or more improvement of the 4-point FWS scale	At 4 weeks: 24U Xeomin (Inco-BoNT-A), 96.4%; 24U Botox (Ona-BoNT-A), 95.7%	This is the only published RCT so far. The results of the placebo-controlled trials have yet to be published

with a sad-looking appearance and considered to be an unsatisfactory outcome.

Two randomized controlled clinical trials were identified focusing on Ona-BoNT-A for the treatment of forehead lines [24,25]. The Keen trial (1994) was a very small, placebo-controlled trial that basically showed that Ona-BoNT-A was effective in reducing forehead wrinkles. The Carruthers trial was a three-arm dose-response trial that clearly showed an advantage of the two higher doses tested. Interestingly, the number of adverse events was not very different between the three arms. Brow ptosis was only observed in the two higher dosage groups, with 21% and 10%. Another trial was identified comparing in a split-face study Ona-BoNT-A and Abo-BoNT-A for three indications [26]. Not surprisingly, the highest efficacy of forehead wrinkle reduction correlated

with most marked reduction in brow elevation. Although no adverse events were reported in this study, a significant inability to lift the brow might be considered also as an adverse event (Table 61.6). This highlights the fact that balance and proportion of facial landmarks may be more important from an esthetic perspective than simply reduction in wrinkles and lines.

### Summary

The evidence for the treatment of the forehead lines is still insufficient. Only three RCTs for two of the three BoNT-A preparations were found. Further studies are needed for this indication to determine the optimal dosage, taking into account not only forehead wrinkle reduction, but also considering reduction in brow elevation for best cosmetic outcome.

**Table 61.6** Studies focusing on the treatment of forehead wrinkles with BoNT-A (different types).

Author Year Country	Study type No. of patients % female Injection points (IP) Dose Duration	Inclusion criteria	Outcome criteria	Results	Comment
Carruthers <i>et al.</i> [24] 2003 USA	RCT 59 100% 8 IP (4 forehead, 2 orbicularis oculi, 2 procerus) 16, 32 or 48U Botox (if only the forehead is considered: 8, 16 and 24U) (Ona-BoNT-A) 44 weeks	Moderate (2) to severe (3) horizontal forehead wrinkles	None (0) or mild (1) on the 4-point FWS	At 2 weeks response rates of 84%, 89%, and 95% at contraction. Higher dosages were associated with a significant trend showing increasing time to relapse	Besides the m. frontalis (elevator) two depressors (m. orbicularis oculi and m. procerus) were treated in this study
Keen <i>et al.</i> [25] 1994 USA	RCT 11 63% 9 IP forehead or 2 IP crow's feet 0.2 cm <sup>3</sup> of Ona-BoNT-A (10U) or placebo	None given	4-point FWS	Mean reduction of 1.3 injection points	Ona-BoNT-A was more effective than placebo
Michaels <i>et al.</i> [26] 2012	RCT 53 98% Three indications: forehead, glabella, and crow's feet Total dosage of 25U Botox (Ona-BoNT-A) or 62.5sU Dysport (Abo-BoNT-A) (with forehead dosages of 6U and 15sU respectively )	Not clear	FWS (from 0 to 3 with subgroups) and eyebrow height measurement	After 90 days 75% (Dysport) and 72% (Botox) of improvement respectively After 150 days 64% (Dysport) and 60% (Botox) of improvement respectively	No significant difference between Ona- and Abo-BoNT-A using a 1:2.5 ratio

**Table 61.7** RCTs focusing on the use of saline with a preservative.

Author Year Country	Study type Study design No of patients/locations	Outcome criteria	Results	Comment
Alam <i>et al.</i> [28] (III/B) 2002 USA	RCT Double blind Randomized Ona-BoNT-A diluted with 5 mL (benzyl alcohol: 9 mg/mL) vs standard saline <i>n</i> = 15 Multiple locations	Percentage of change of discomfort	15 (100%) patients reported less pain in the side of their face treated with the product reconstituted with preservative containing saline ( <i>P</i> = 0.001). Pain on the preservative-containing side was 54% less	Small trial
Sarifakioglu and Sarifakioglu [29] (III/B) 2005 Turkey	CT Single blinded Not randomized 2 mL dilution (benzyl alcohol: 9 mg/mL) <sup>a</sup> vs standard saline <i>n</i> = 93 Multiple locations (upper face, crow's feet, <i>n</i> = 60, neck, <i>n</i> = 15, axillary region <i>n</i> = 18)	VAS (0–10)	1.2 (with preservative) vs 4.5 for the upper face 0.6 (with preservative) vs 3.9 for the neck 0.9 (with preservative) vs 5.1 for the axillary region ( <i>P</i> = 0.000)	The preservative containing solution was always applied on the right side
Allen and Goldenberg [30] 2012 USA	RCT Randomized Double blind Split-face design Dysport (Abo-BoNT-A) Diluted with 2.5 mL of preserved bacteriostatic 0.9% sodium chloride injection, USP (Hospira, Inc., Lake Forest, IL) or standard saline <i>n</i> = 20 (glabella and crow's feet)	VAS (0–10)	90% of patients reported less pain on the side injected with preserved saline than on the side injected with preservative-free saline. Pain on the preserved saline side was 60% less than on the preservative-free side	0.1 mL injected per injection point

VAS: visual analogue scale.

<sup>a</sup>Probably (the source of the benzyl alcohol was Abbot Laboratories, North Chicago, IL, USA).

### What is the evidence for reducing injection pain?

BoNT-A is delivered by subcutaneous or intramuscular injection. Pain thresholds amongst patients vary quite considerably, but reduction in injection pain would be welcomed by all.

There are several consensus statements in the literature advocating the use of preservative in the saline which is used for the dilution of the botulinum toxin [27] Here, we examine the evidence for its use.

### Randomized controlled trials and meta-analysis

There is no meta-analysis available to date using saline with preservative to reduce injection site pain. A total of three clinical trials can be found (Table 61.7).

Three small studies focused on the effect of adding a preservative to the saline used for the dilution of BoNT-A. Two were small randomized double-blinded RCTs, one using 100U of Ona-BoNT-A with a 5 mL dilution and one using a 2.5 mL dilution for

Abo-BoNT-A [28,30]. Similar results are reported from a nonrandomized trial by Sarifakioglu and Sarifakioglu [29]. All three trials point to a decreased pain sensation when adding saline with a preservative (benzyl alcohol) to the different toxins.

The reasons for that might be the anesthetic qualities of the added benzyl alcohol [31] or a more physiological pH or osmotic pressure (A. Pickett personal communication). However, one has to be aware that the addition of benzyl alcohol as a preservative may carry a small risk of contact sensitization [32].

### Summary

To summarize, although the evidence is limited to small trials only, the results suggest reduction in injection pain with the addition of saline with benzyl alcohol as preservative. As injection pain reduction should be a goal of all injected treatments, the use of saline with benzyl alcohol as preservative might be worth a try. Saline with benzyl alcohol as preservative is not currently available everywhere (e.g., not in Germany).

### What is the evidence that BoNT-A may be used for the prevention of wrinkles and folds?

With chronologic and exogenous aging, wrinkles and lines become more apparent, and studies conclude glabellar and forehead lines show significant association with advancing age [1]. Prevention of an aged appearance can therefore be associated with slowing the development of wrinkles and folds, so it is appropriate to explore the question of the evidence that BoNT-A might be a helpful tool for wrinkle prevention. Not surprisingly, the evidence that can be found is very limited. There are no cohort studies, although theoretically a nested case-control study in a large cohort study designed for a different purpose might be an option. Randomized clinical trials – even case cohorts – are not feasible for time periods which extend to several years.

However, two studies were found using Ona-BoNT-A: (1) a twin study (just one pair of identical twins) from Binder [33] and a case cohort study from Dailey *et al.* [34]. In the Binder study, identical twin sisters are described. One received Ona-BoNT-A in the forehead and glabellar region (approximately two to three times each year over 13 years). The other twin received the product only twice (in the forehead and glabellar region, 3 and 7 years previously). Visible forehead and glabellar lines were not evident in the regularly treated twin but were evident in the minimally treated twin. Untreated facial areas (e.g., nasolabial folds) showed comparable aging in both twins.

In the Dailey study (2011), patients ( $n = 45$ ) received repeated injections of 20 U Ona-BoNT-A at 4-month intervals in the glabellar area. Wrinkle severity gradually improved over a total study period of up to 26 months and was still better than baseline at the last time point (6 months after the last injection). A similar study on Inco-BoNT-A exists. In this analysis, phase 3 trial data on the glabella were reanalyzed for repeated injections up to 24 months and eight injection visits with mostly 20 U (although some arms started with 10 or 30 U). Efficacy gradually improved from the first to the last visit [35]. A comparable study is the study of Moy *et al.* [37] focusing on Abo-BoNT-A in the treatment of the glabella. However, in this study the total observation period was limited to 13 months and five consecutive treatments only.

### Summary

The evidence that BoNT-A prevents the signs of aging is very limited. Besides the twin study that at least covers a 13-year period,

there are only two 2-year studies. Both studies support a possible preventive effect of repeated BoNT-A treatments. Case-control studies should be encouraged with the aim to evaluate minimum doses required and injection intervals necessary.

### Further questions

All the interesting and relevant questions relating to the esthetic use of BoNT-A could not be covered in this chapter. However, an overview of questions which focus on specific anatomical areas, modes of injection, and the intervention as preventative treatment has been provided in this chapter.

### Key points

The treatment with BoNT-A is well established; however, there are still significant gaps in our knowledge base. Even for the four questions we examined, available evidence was extremely variable and often fraught with confounding factors.

### Indication-based questions

Concerning the optimal dosage for the glabella, there is a large amount of evidence arising from clinical trials as well as case cohorts. Based on these trials, the optimal dosage is estimated to be 50 U Abo-BoNT-A (Dysport/Azzalure) and 20 U Ona-BoNT-A (Botox/Vistabel). Nevertheless, one has to be aware that all except one study were performed in overwhelmingly female populations. Therefore, this dosage may be considered a starting dose in men and may be adjusted to muscle mass and muscle activity. In contrast, for the forehead, the available data are very limited. So far there is enough evidence for efficacy, but not for the optimal dosage or injection points. Furthermore, the endpoints of maximum reduction in glabellar lines must be placed into the entire facial esthetic context.

### Procedure-based question

There is some evidence that the addition of preservative may decrease injection pain. Based on this evidence, the usage of saline with preservative (benzyl alcohol) may be suggested. However, larger clinical trials are necessary to turn this into a sound recommendation. It should also be evaluated whether the use of preservative-containing diluents affects the product in any way.

### Prevention through long-term BoNT-A treatment

Finally, the use of BoNT-A as a preventive agent must be considered. Here, the evidence is very scarce. We have a case report and two case series of different durations pointing to a positive, preventive effect of a regular treatment with BoNT-A. It is clear more evidence is needed; for example, a case-controlled study focusing on long-term treated and nontreated patients with controls for other preventive factors would be very helpful.

### CHAPTER 62

# Cutaneous lupus erythematosus

Susan Jessop<sup>1</sup> and David Whitelaw<sup>2</sup>

<sup>1</sup>Division of Dermatology, Groote Schuur Hospital and University of Cape Town, Cape Town, South Africa

<sup>2</sup>Rheumatology Unit and Cardiology Unit, Tygerberg Hospital and Stellenbosch University, Tygerberg, South Africa

## Background

### Definition

Systemic lupus erythematosus (SLE) is a multisystem inflammatory disease characterized by the presence of a wide variety of autoantibodies. Skin involvement is common, being present in 55–90% of cases [1]. The characteristic skin lesions can be divided into acute, subacute, and chronic subsets [2]. The acute forms include the malar (butterfly) rash, papular lesions, urticaria, vasculitic lesions, hair loss, and painless mouth ulcers. Subacute cutaneous lupus erythematosus (SCLE) is an uncommon form of cutaneous lupus, described as a clinical subset by Sontheimer *et al.* in 1979 [3]. Chronic discoid lupus erythematosus (DLE; Figure 62.1) tends to be the most persistent of the skin lesions and may lead to unsightly scarring. It is most frequently seen as an isolated entity, but may also occur in SLE. Lupus panniculitis (lupus profundus), neonatal lupus, lupus tumidus, and bullous lupus are less commonly encountered forms of the disease.

### Incidence/prevalence

Accurate incidence or prevalence figures are difficult to obtain because different methods have been used in the reported studies. Many series are hospital based and probably do not reflect the true incidence. Published figures suggest an increasing incidence, but apparent changes in incidence may be because of greater awareness of the condition.

### Etiology

Lupus seems to result from an interaction between genetic, hormonal, and environmental factors [4]. SLE is known to be associated with the production of a large range of autoantibodies. In certain specific subsets, such as neonatal lupus, their role in pathogenesis is now clearly established. The greatest risk factor is female sex (the female:male ratio is 9:1), and the highest prevalence is in the child-bearing age group. The genetic hypothesis is supported by familial

clustering of lupus and the association between certain human leukocyte antigen types with particular subsets of lupus [5,6].

Evidence for a viral etiology has not been conclusive [7]. A detailed discussion is beyond the scope of this text.

### Prognosis

Mortality is associated with severe systemic disease, and is highest with renal and central nervous system involvement. Skin involvement, while not associated with mortality per se, frequently produces scarring, with considerable morbidity, both physical and psychological.

### Diagnostic tests

Diagnosis of cutaneous lupus can generally be made by clinical examination. A skin biopsy is required in cases of doubt. Autoantibody tests may be positive in cutaneous lupus but do not necessarily imply systemic disease. Specific antibodies, notably antiRo antibody, are strongly associated SCLE and neonatal lupus.

### Aims of treatment

Doctors aim to stop inflammation and prevent further damage. Unfortunately, there may be marked residual pigmentary changes (most marked in dark-skinned individuals) and skin atrophy. People with facial DLE may be disappointed by this outcome, as quality of life remains impaired. Early diagnosis and treatment are important to prevent extensive scarring.

### Relevant outcomes

- Improvement in participant global score;
- improvement in redness, thickness or scaling of lesions;
- reduction in extent of lesions;
- total clearing;
- no change or worsening of skin lesions;
- development of new lesions.

**Figure 62.1** Lesions of DLE, showing scarring and changes in pigmentation.

A scoring system, the cutaneous lupus activity and severity index (CLASI), has been proposed to quantify activity and damage in cutaneous lupus [8]. CLASI is a promising move towards improved consistency in clinical trials.

### Methods of search

We searched the Cochrane Library (2012), Medline (1950s to June 2012), Embase (1988 to June 2012) Science Direct (2001–June 2012) and the Cochrane Central Register of Controlled Trials. We included all randomized controlled trials (RCTs) and controlled trials. Where no controlled trials were found, we report briefly on observational studies.

## Questions

### What are the effects of antimalarial treatment in cutaneous lupus?

#### Chloroquine or hydroxychloroquine

##### Benefits

We found one systematic review [9] and two RCTs.

Ruzicka *et al.* studied 39 people with DLE and 19 with SCLE, comparing hydroxychloroquine, 400–1200 mg/day, with acitretin, 50 mg/day, over 8 weeks [10]. Treatment arms were similar in terms of age, sex, and extent of disease, but SCLE was more strongly represented in the hydroxychloroquine group. Complete clearing or marked improvement occurred approximately equally in the two groups (50% vs 46%). Four participants dropped out because of treatment side effects (all in the acitretin arm) and three because of total clearing of lesions (all in the hydroxychloroquine arm). In the study by Bezerra *et al.*, 33 people were randomized to receive either 100 mg/day clofazimine (16 participants), or 250 mg chloroquine daily (17 participants). Skin lesions ranged from chronic discoid to acute lupus. There was no significant difference in the response rates at 6 months: 82% in the chloroquine group and 75% in clofazimine group [11].

We found three RCTs of antimalarials in non-life-threatening SLE. In a Canadian study, people taking hydroxychloroquine for

SLE were randomized to continue the drug ( $n = 25$ ) or to take placebo ( $n = 22$ ) [12]. At 6 months, 16 of the 22 on placebo and 9 of 25 in the active arm had experienced disease flares, a 2.5-fold increase in the untreated participants. Skin lesions were not specifically described. Williams *et al.* compared hydroxychloroquine, 400 mg/day, with placebo in 71 people with mild SLE over 48 weeks [13]. Although the study was designed to determine the effect of the trial drug on joint disease, the cutaneous, neurological, and cardiopulmonary systems were also evaluated. Placebo and active groups both improved, but overall there was no significant difference in the outcome of skin lesions between the two groups at any stage in the study. The third RCT involved 23 participants, 11 randomized to receive chloroquine and 12 to receive placebo [14]. The chloroquine-treated group showed less “skin activity” than the placebo group (9% compared with 42%; 95% confidence interval, 9–74%), but skin lesions and outcome measures were not clearly described. Overall, patients taking chloroquine experienced fewer flares and required lower doses of steroids.

We found one double-blind but nonrandomized trial comparing hydroxychloroquine with placebo in DLE [15]. Forty-nine people were treated for 1 year: 24 with hydroxychloroquine and 25 with placebo. Results at both 3 and 12 months indicated that hydroxychloroquine was superior to placebo.

We found many observational reports of chloroquine or hydroxychloroquine in cutaneous lupus [16–22]. Christiansen reviewed 13 case series up to 1956 and added his own, giving data on a total of 414 people treated in these studies [16]. He noted that 265 (64%) experienced complete clearing or marked improvement. His series was notable for the duration of treatment (18–53 weeks) and the careful description of outcome, but was flawed by the absence of a parallel control group and the high dose of chloroquine (500–750 mg daily). An open trial of chloroquine in patients with lupus tumidus suggests that it may be useful in this condition [23].

##### Harms

Adverse events were described in 17 of 30 people taking hydroxychloroquine [10]. Symptoms included dry skin ( $n = 8$ ), itching ( $n = 5$ ), and gastrointestinal disturbance ( $n = 5$ ). The most frequent side effects described by Kraak *et al.* were gastrointestinal (eight in hydroxychloroquine arm vs three in placebo arm) and cutaneous (four in hydroxychloroquine arm vs three in placebo arm) [15]. One person developed a severe retinopathy while taking hydroxychloroquine, after having taken chloroquine for several years at a higher than recommended dose (1200 mg/day). Retinal toxicity is discussed by Houpt [24]. There is little evidence to support regular blood monitoring [25]. A meta-analysis of toxicities emphasizes the low level of toxicity of antimalarials [26]. A small RCT in 20 pregnant women with lupus erythematosus, 10 taking hydroxychloroquine, showed no adverse effects in either mothers or babies [27].

##### Comments

While chloroquine and hydroxychloroquine are currently “standard of care” in cutaneous lupus, trials are flawed by a lack of placebo group and inclusion of different types of cutaneous lupus erythematosus (CLE). SLE trials do not provide clear descriptions of mucocutaneous lesions, making interpretation difficult.

We have not found evidence of a difference between hydroxychloroquine and chloroquine in the treatment of CLE or any information regarding dosage in CLE, in relation to either efficacy or toxicity.

## Amodiaquine and quinacrine

### Benefits

We found no RCTs or controlled trials. Wallace has reviewed the literature on quinacrine, finding 20 observational trials [28]. Cutaneous subsets and outcome measures were not clearly defined. Smaller observational studies of amodiaquine have been published [29,30].

### Harms

Central nervous system, gastrointestinal, and cutaneous adverse effects have been reported.

## Combinations of antimalarials

### Benefits

We found no controlled trials. There are five case series and a case report of the combination of chloroquine and quinacrine [31–35].

### Harms

Yellow skin discoloration, photophobia, insomnia, and nausea were noted by some people but did not usually require withdrawal of treatment.

## Intralesional antimalarials

### Benefits

We found two observational studies of intralesional chloroquine [36,37].

## What are the effects of systemic steroids in cutaneous lupus?

### Oral steroids

#### Benefits

We found no RCT. We found one observational study and a case series in combination with an antimalarial [38,39].

#### Harms

“Mild cushingoid features” were noted in two people taking oral steroids during the above study [38]. A recent review of side effects of low-dose glucocorticoids suggests that the harms associated with these agents may not be as serious as traditionally believed [40].

#### Comments

There is not sufficient evidence to judge the efficacy of oral steroids in cutaneous lupus.

## What are the effects of other oral agents in cutaneous lupus?

### Clofazimine

#### Benefits

We found one small RCT comparing clofazimine with chloroquine [11]. There was no significant difference in the response rates at 6 months: 82% (14/17) in the chloroquine group and 75% (12/16) in the clofazimine group. We found four observational studies [41–44].

#### Harms

A pink or red discoloration and darkening of the skin resulting from the deposition of clofazimine has been recorded. Dry skin, keratosis pilaris, and a transient rise in transaminases have been reported. Arbiser and Moschella have reviewed the toxicity of clofazimine [45].

### Comments

A small RCT suggests that clofazimine may be useful in treatment of cutaneous lupus but the quality of evidence is poor, due to small numbers and lack of a placebo group.

## Dapsone

### Benefits

We found no RCTs or controlled trials of dapsone. Case series and case reports describe the use of dapsone in people with various forms of cutaneous lupus, in particular bullous lupus and urticarial vasculitis [46–56]. Data are summarized by Duna and Cash [57].

### Harms

Side effects described include nausea, vomiting, headache, fatigue, hemolysis, methemoglobinemia, and leucopenia. Mok *et al.* have reviewed the toxicity of dapsone [58].

### Comments

There is no adequate evidence to guide clinical practice.

## Methotrexate

### Benefits

We found no RCTs, but did find one controlled trial of methotrexate in systemic lupus [59]. A double-blind study reported that 12 of 20 people in the active arm and 16 of 21 in the placebo arm had cutaneous lesions, declining to three in the active arm but remaining unchanged in the placebo group. The skin lesions and outcome measures are not described. A retrospective study of cutaneous lupus recorded an improvement in 42 of 43 people [60]. A second retrospective study of 139 patients had similar findings [61]. We found small observational studies and case reports describing improvement in a variety of skin lesions of lupus [62–71].

### Harms

Problems encountered included dyspepsia, mouth ulcers, thrombocytopenia, and a rise in transaminases, but no increased rate of infection. Discussions of methotrexate toxicity have been published [72,73].

### Comments

The evidence for an improvement in skin lesions is too limited to allow any definite conclusions, although it may be a useful drug.

## Retinoids

### Benefits

We found one RCT, in which there was no placebo group and the two treatment groups were not matched for type of CLE [10]. We found three uncontrolled trials, and several case reports of oral or topical retinoids in chronic cutaneous lupus [74–84].

### Harms

Retinoids are teratogenic. Side-effects were recorded more commonly with acitretin (27 of 28 people) than with chloroquine [10]. Dry lips, dry skin, itching, and hair loss were most common. Raised serum triglycerides were noted in five of 18 people. All improved with dose reduction and resolved when therapy was discontinued. Retinoid toxicity has been reviewed by Lowe and David [85].

### Comments

There is insufficient evidence to assess the value of retinoids in cutaneous lupus. The available evidence suggests that efficacy is

similar to that of hydroxychloroquine, but that side effects appear to be more frequent.

## Thalidomide

### Benefits

We found no RCTs or controlled trials. There have been numerous uncontrolled studies, and several case series are reported [86–97]. In an uncontrolled Brazilian study on refractory cutaneous lupus, 60 of 65 participants experienced complete remission. Lesions ranged from chronic DLE to acute rashes. There was an 82% relapse rate on stopping the drug [86]. Similar results have been reported in smaller series [87,96].

### Harms

Thalidomide is teratogenic. Varying incidences of paresthesia and electroneurographic changes have been reported. Other side effects include drowsiness, dizziness, vertigo, dreams, mood changes, weight gain, and constipation. Calabrese and Fleischer have reviewed the side effects of thalidomide [98]. There is a single case report on the use of lenalidomide in the treatment of DLE [99].

### Comments

The evidence for efficacy is inadequate, relying on observational studies and case reports.

### Implications for clinical practice

There is no evidence from controlled trials to support the use of thalidomide in CLE.

Current recommendations for people taking thalidomide include patient education about risks of pregnancy and significance of paresthesia, a three-monthly clinical examination, and electrophysiological studies, if indicated.

## Mycophenolate mofetil

### Benefits

A number of studies, including an open trial, case series, and case reports, have been reported, with conflicting results [100–104]. An RCT for induction treatment of renal lupus found that cutaneous lupus improved, but no details are given [105].

### Harms

Mycophenylate mofetil (MMF) appears to be generally well tolerated.

### Comments

Current data make it impossible to comment on the possible role of MMF in treatment of CLE.

## What are the effects of biological agents in cutaneous lupus?

### Rituximab

#### Benefits

An RCT has failed to demonstrate a difference between rituximab and placebo in people with moderate to severe systemic lupus. A number of patients with muco-cutaneous lesions were included, but details are insufficient to allow any conclusions [106].

Analysis of French rituximab registry data demonstrated a 70% improvement in cutaneous lesions among people with SLE [107]. The study was seriously flawed, as it was not a trial, rituximab was not compared with another agent, participants were not equally distributed, and skin lesions were not described. There are case

reports and case series describing the use of rituximab in SLE. These have been summarized [108].

#### Harms

Severe adverse reactions have been reported, including infusion reactions and severe infection [107].

#### Comments

Currently, there is no convincing evidence to support the use of rituximab in the treatment of CLE.

## Belimumab

### Benefits

We found two RCTs of placebo versus belimumab 10mg/kg [109,110]. Belimumab was a little more effective than placebo in reducing flares of SLE (SLE response index at 52 weeks was 43.2% vs 33.5%). No analysis of skin involvement was reported. A study using the same design in different populations showed similar results.

### Harms

Infusion reactions and severe infection were reported in both placebo and active groups in both studies.

### Comments

There is insufficient evidence to support the use of belimumab in CLE.

## Efalizumab

### Benefits

A small open trial and a case report in cases of DLE have been reported [111,112].

### Comments

No comments are possible owing to paucity of data.

## Other biological agents

Tumor necrosis factor alpha antagonists: the complex interaction between these agents, SLE, and skin lesions is discussed elsewhere [113].

The use of other biological agents has been directed at controlling systemic flares, and there is currently no evidence to guide clinicians in their use in CLE [114].

## Other systemic agents

Short series or case reports exist for a wide range of agents, including azathioprine [115–119], cyclosporine [120–123], phenytoin [124], sulfasalazine [125,126], immunoglobulins [127–129], and interferon alpha [130,131], but there is no robust evidence for their effectiveness and we will not discuss these agents further.

## What are the effects of topical agents in cutaneous lupus?

### Topical steroids

#### Benefits

We found two RCTs of potent topical steroids [132,133]. The first study compared 0.025% fluocinolone acetonide and 0.1% betamethasone valerate used for 3 weeks [132]. Symmetrical skin lesions were used, and the participants were randomized to use the creams on the right or left side of the body. Betamethasone valerate appeared to be superior in 15 of 25 (60%) participants.

In a 12-week crossover study, 0.05% fluocinonide (a potent steroid cream) was compared with 1% hydrocortisone (a low-potency steroid cream) [133]. After 6 weeks, an excellent response was seen in 10 of 37 people (27%) using fluocinonide and in 4 of 41 people (10%) using hydrocortisone cream. This result suggests that high-potency steroid cream is more effective than low-potency steroid cream.

We found one controlled trial, comparing fluocinolone acetone with ointment base; 17 of 20 people (85%) showed greater improvement with the steroid than with base alone [134].

We found six observational studies of topical steroids [135–140]. A total of 263 people were treated in these trials, 220 (84%) of whom experienced complete clearing or marked improvement in the treated areas.

### Harms

Skin irritation was noted by three people using hydrocortisone, and a burning sensation by one person using fluocinolone [133]. No side effects were reported in the other controlled trials. In the uncontrolled trial of methylprednisolone aceponate in 322 people with various dermatoses, local side effects such as burning, itching, pain, and inflammation were observed in 22 people (7%) [136]. Toxicity of topical steroids has been reviewed by Hengge *et al.* [141].

### Comments

All the controlled trials of topical steroid were of short duration, but the evidence supports the use of potent topical steroids in DLE.

Although topical steroid use may be associated with skin atrophy, it is probably relatively unimportant in DLE, which produces severe scarring and atrophy in itself.

## Intralesional steroids

### Benefits

We found four case series, involving 114 people. There was marked improvement or clearing in 91 participants (80%) [142–145].

### Harms

Skin thinning (atrophy) was noted in a small percentage of people in the above studies.

## Calcineurin antagonists

### Benefits

We found four RCTs and one nonrandomized study.

An RCT involving 20 patients comparing 0.1% tacrolimus with 0.05% clobetasol found no difference [146]. Small numbers, lack of intention to treat, mixed subsets of CLE, and short duration limit the value of this study.

A placebo-controlled randomized trial found 0.1% tacrolimus to be superior to the vehicle initially [147]. The beneficial effect was not sustained at 84 days.

An RCT comparing 1% pimecrolimus with 0.5% betamethasone valerate found the two agents comparable at 8 weeks [148]. Small numbers reduce the value of their findings.

An RCT comparing 1% pimecrolimus with placebo in 25 patients with DLE and SCLC found no difference [149].

There are numerous cases series and case reports. Sticherling includes a comprehensive summary of all published work on this topic [150].

### Harms

RCTs using these agents for other conditions have identified irritation and a sensation of burning as common in the early stages of treatment. Carcinogenesis has been raised as a potential concern.

### Comment

Topical tacrolimus appears to be as effective as ultrapotent topical steroids and the side-effect profile may be better.

## What are the effects of nondrug treatments in cutaneous lupus?

### Sunscreens

#### Benefits

We found one double-blind intra-individual trial on the efficacy of three commercially available sunscreens in the prevention of the skin lesions in SLE. Protective efficacy on exposure to ultraviolet light varied from 30 to 100% [151]. In a placebo-controlled RCT examining response to ultraviolet light, broad-spectrum sunscreen significantly reduced ultraviolet-induced skin lesions in people with CLE [152].

A clinical RCT was conducted and completed at the end of 2013 (registration no. NCT01146444).

We found one further open-label study [153].

#### Comments

There is evidence to suggest that sunscreens are beneficial in the prevention of CLE.

## Surgery

### Benefits

We found no RCTs or controlled trials. We found six reports describing 17 patients treated with either dermabrasion or excision and grafting [154–159].

#### Comments

There is insufficient evidence to comment about surgery.

## Ultraviolet light

### Benefits

We found one controlled trial of UVA1 (350–440 nm) in 11 people with systemic lupus [160]. Disease activity was measured by the SLE disease activity index (SLEDAI score), a 24-item score that measures SLE activity [161], but skin lesions were not specifically described. A nonsignificant improvement in Raynaud's phenomenon and rash (type not specified) was noted.

We found two observational studies [162,163]. Sonnischen *et al.* successfully treated a person with DLE [164]. We also found case reports describing the use of extracorporeal photopheresis in cutaneous lupus [165–167].

### Harms

No adverse events were reported in the above studies.

#### Comments

Although the trial reported by Polderman *et al.* [160] was double blind, the findings cannot be interpreted with confidence because the numbers were small and the two arms (nine active treatment, two placebo) were disproportionate.

There is currently insufficient evidence to comment on the use of this modality. There is no evidence to indicate the relative risk of inducing a flare in this light-sensitive disorder.

## Laser treatment

### Benefits

We found no RCTs or controlled trials. We found two case series and five case reports [168–174] using various forms of laser.

## Harms

Transient pigmentation was seen in some people.

## Comment

Data are too fragmented to allow any conclusions.

### Key points

- We found limited evidence that potent topical steroids, tacrolimus cream, chloroquine, and acitretin are beneficial in cutaneous lupus.
- We found very few RCTs of treatment of cutaneous lupus and only a few controlled trials.
- We found many uncontrolled studies, some involving large numbers of people, followed for several years, particularly relating to older treatments.

## Background

### Definition

Dermatomyositis (Figure 63.1) is one of the idiopathic inflammatory myopathies [1,2]. In a set of criteria to aid in the diagnosis and classification of dermatomyositis and polymyositis, first proposed by Bohan and Peter in 1975 [3,4], four of the five criteria are related to the muscle disease:

- 1 progressive proximal symmetrical weakness;
- 2 elevated muscle enzymes;
- 3 abnormal electromyogram (EMG);
- 4 abnormal muscle biopsy;
- 5 presence of compatible cutaneous disease.

Unfortunately, these criteria are not sensitive in identifying the full spectrum of patients with idiopathic inflammatory dermatomyopathy. It has subsequently been recognized that there are many patients with compatible cutaneous disease who never develop any manifestation of muscle disease, such as weakness or abnormal changes on muscle biopsy, EMG, or magnetic resonance imaging (MRI) studies. Sontheimer [5] has used the term “amyopathic dermatomyositis” (ADM) for those who fulfill these criteria for at least 6 months in the absence of disease-modifying therapies such as corticosteroids and/or immunosuppressive agents. Juvenile dermatomyositis is traditionally defined as disease onset before 16 years of age.

### Incidence/prevalence

Dermatomyositis is a rare disorder. It may be slightly more frequent in women, and all ethnic groups are affected. It has been estimated that dermatomyositis or its related condition polymyositis occur in 5.5 patients per million. However, this figure includes patients with polymyositis and dermatomyositis and most likely does not include patients with ADM. More recently, the incidence of clinically ADM was noted to be 2.08 (95% confidence interval [CI], 0.39–3.77) per 1 million persons in a population-based study, making these cases comprise approximately 20% of all dermatomyositis cases [6].

## Etiology

The etiology of dermatomyositis is unknown. The mechanism behind the skin disease likely differs from that of the muscle disease. Dermatomyositis appears to result from a complement-mediated inflammation and destruction of capillaries with subsequent ischemic muscle damage, whereas polymyositis is thought to be caused by cytotoxic CD8+ T cells damaging muscle fibers.

### Prognosis

In the patient with ADM, the prognosis is good in the absence of malignancy or pulmonary disease. For patients with muscle disease, the prognosis depends on the severity of the muscle disease, the presence of lung disease, esophageal dysfunction, cardiac disease, and/or malignancy. Children and adolescents with dermatomyositis often develop calcinosis, which can result in disability or discomfort, but are not considered to have an increased risk of malignancy.

### Diagnostic tests

The diagnosis of ADM is confirmed by clinical–pathological correlation. The pattern of the skin disease is relatively characteristic, and when an interface dermatitis is demonstrated on skin biopsy, the diagnosis may be relatively firm. However, some subtle cases can be confused with cutaneous lupus, and immunofluorescence studies of skin biopsies can be helpful in making this distinction [7,8]. For patients with myositis, the diagnosis of dermatomyositis is confirmed by the presence of typical muscle symptoms and findings, together with elevated muscle enzymes, or an abnormal EMG, MRI, and/or an abnormal muscle biopsy.

### Aims of treatment

Treatment provides control of the muscle inflammation and allows the patient to return to normal function; the patient might otherwise become disabled from the weakness. The skin disease is often symptomatic, often associated with prominent pruritus, and is cosmetically displeasing. The goal of therapy is therefore to relieve the

**Figure 63.1** This patient presented for the evaluation and treatment of her skin condition, which had been present for the past 6 months. A previous biopsy had revealed an interface dermatitis and her antinuclear antibody was positive. A working diagnosis of lupus erythematosus was made. Treatment with sunscreens and topical corticosteroids were ineffective. Hydroxychloroquine administration resulted in a severe cutaneous drug reaction that required hospitalization. Clinical examination on referral revealed cutaneous findings of dermatomyositis.

symptoms and improve the patient's quality of life. Some patients with dermatomyositis have an associated malignancy, and treatment of the malignancy may in some patients result in a control of the disease process. In children with dermatomyositis, treatment also aims to prevent calcinosis, or to eradicate calcinosis if it does occur.

### Relevant outcomes

Return of the patient to normal muscle function and improvement in the quality of life for those with skin disease are important measures of outcome. Improvement in lung function is important in patients with pulmonary disease. In addition, identification and treatment of a potential malignancy is important. Outcome measures of muscular and extramuscular function have been defined [9,10]. In addition, outcome instruments to evaluate the response of cutaneous dermatomyositis to therapy have recently been developed. The Cutaneous Dermatomyositis Disease Area and Severity Index (CDASI) and the Dermatomyositis Skin Severity Index (DSSI) have recently been validated and will be valuable for future studies [11–13].

### Methods of search

The databases of the Cochrane Skin Group, the *Cochrane Library* to issue 1, 2012, and Medline and Embase between 1968 and July 2012 were searched for articles reporting trials of therapy of skin disease, or dermatomyositis, or the relationship of dermatomyositis to malignancy. Both Embase and Medline were searched using the Ovid search engine at Nottingham University. The searches involved the following terms:

- The relationship of dermatomyositis to cancer (malignancy, neoplasia).
- Treatment of skin disease in patients with dermatomyositis (idiopathic inflammatory myopathy, polymyositis, juvenile dermatomyositis).
- Treatment of dermatomyositis with any of the following agents: antimalarials (hydroxychloroquine, chloroquine), corticosteroids (prednisone, methylprednisolone), dapsone, thalidomide, methotrexate, mycophenolate mofetil, azathioprine, intravenous immunoglobulin (IVIG), rituximab, etanercept, infliximab, adalimumab, eculizumab, abatacept, anakinra, physiotherapy, physical therapy, plasma exchange, plasmapheresis, cyclophosphamide,

cyclosporine, tacrolimus, FK506, probenecid, colchicine, minocycline, alendronate, pamidronate, diltiazem, warfarin, and sunscreens.

## Questions

### What is the risk of malignancy in the patient with dermatomyositis or amyopathic dermatomyositis?

Population-based studies from Scandinavia clearly demonstrate an increase in the risk of cancer in dermatomyositis, while the modest increase in polymyositis is explained primarily by diagnostic suspicion bias and is not reflected in an increase in mortality (Table 63.1) [14–21]. More recent American and South Australian studies also support this finding [22,23]. It is also clear that these patients have an increased risk for ovarian cancer [14,16,18,19,24–26]. What has not been clear is whether these data are applicable to other populations such as Southeast Asians, African-Americans, or other ethnic groups. More recently, data from Southeast Asian populations support a higher risk of malignancy in patients with dermatomyositis than with polymyositis as well [27–29].

A study from Australia [15] called into question much of the data that have been based on clinical diagnosis. It does appear that dermatomyositis and polymyositis are not the same disease and that their histopathological abnormalities differ significantly and are recognizable by muscle pathologists. Therefore, there may exist a group of patients who were thought to have polymyositis but who might be classified as having dermatomyositis sine dermatitis. This concept is intriguing and might explain why some studies have shown little difference in the prevalence/incidence of malignancy in the two groups. In addition, the existence of this subset might well explain some of the differences that are observed in the studies of therapy (see later).

Regarding patients with ADM, a systematic review of the available published cases previously suggested that these patients are also at increased risk for cancer, as well as interstitial lung disease [17]. Since that time, additional literature has supported that patients with amyopathic disease still have a risk for associated malignancy [30]. In one retrospective review based in the USA, the prevalence of interstitial lung disease was found not to be different between patients with classic and ADM [31]. Other data suggest that patients with skin-limited disease may even have an increased risk of pulmonary disease in some populations. One of the difficulties regarding investigations of associations with ADM relates to the manner in which ADM is diagnosed. Because the Sontheimer criteria do not require any testing beyond muscle enzymes, many of the patients defined as having ADM might not actually have amyopathic disease if they were analyzed using all of the available modalities (MRI, muscle biopsy, etc.).

Another issue that is discussed almost universally in the case-control studies is whether the use of immunosuppressive drugs is associated with an elevated risk of subsequent malignancy. In the Scandinavian studies [14,16,18,19], it appears that there is no increase in the prevalence of malignancy in patients who have been treated with an immunosuppressive agent; however, there are many individual case reports of subsequent malignancy in dermatomyositis patients. Several reports [32,33] have linked the use of methotrexate with lymphoma associated with Epstein-Barr virus. Some, but not all, of these patients can have a spontaneous resolution of their lymphoma when the drug therapy is stopped.

### Are there clinical or laboratory findings in dermatomyositis patients that suggest underlying malignancy?

Several studies have suggested that there might be certain clinical or laboratory features that are associated with a greater risk of malignancy (Table 63.2) [14,18,20,34–59]. Most studies, including population-based studies from Scandinavia and Scotland, have shown that advanced age is a significant risk factor for malignancy [14,18,20]. Clinical findings of severe vasculopathy (or vasculitis), such as cutaneous necrosis, ulceration, nodules, and/or periungual infarcts, have also been associated with malignancy [42,44,45, 51,54,60]. Although many studies claim that these findings represent vasculitis, most of them do not present skin biopsy data. Hunger *et al.* provide the only biopsy-based data that cutaneous vasculitis may be a sign of internal malignancy [43]. However, the numbers are too small for firm conclusions to be drawn, and other studies have rejected such an association [49,50,52]. Elevated erythrocyte sedimentation rates have been correlated with malignancy. In contrast, patients with arthralgia/arthritis, Raynaud's, interstitial lung disease, and certain autoantibodies, findings that can be found in association with each other in the "antisynthetase syndrome," have lower prevalences of malignancy in many studies [56]. In general, there have been no consistent associations with regard to muscle disease severity (i.e., strength or enzymes), cutaneous findings (other than the necrosis), or constitutional symptoms that appear to distinguish idiopathic from paraneoplastic dermatomyositis.

Novel sets of autoantibodies have been found to be associated with certain clinical subsets of dermatomyositis. In particular, cancer-associated dermatomyositis, has been noted to be associated with the anti-p155 autoantibody [57–59]. Anti-CADM-140 autoantibodies are associated with clinical ADM, and in some populations rapidly progressive interstitial lung disease, whereas anti-Mi-2 autoantibodies are associated with classic dermatomyositis without either malignancy or pulmonary disease [59]. One series has suggested that patients with anti-CADM-140 autoantibodies have a characteristic cutaneous presentation suggestive of severe vasculopathy [61]. In addition, it has recently been demonstrated that most patients with malignancy-associated dermatomyositis have antibodies to either transcription intermediary factor 1 $\gamma$  (TIF-1 $\gamma$ ) or nuclear matrix protein NXP-2 [62]. These autoantibodies may be useful for diagnosing certain subsets of clinical disease in dermatomyositis in the future, and therefore aid in guiding disease management.

### How should the patient with dermatomyositis/amyopathic dermatomyositis be assessed for possible cancer?

The search for malignancy in patients with dermatomyositis should include a careful history, full physical examination, and standard laboratory evaluation (complete blood count, comprehensive metabolic panel, and stool Hematest). Any abnormalities found should be thoroughly investigated. It remains controversial whether age-appropriate malignancy screening versus more aggressive malignancy screening is supported by the best available evidence. At the very least, a malignancy work-up should include a chest radiograph as well as tests that would be ordered in a "healthy" person of the same age, sex, and ethnic group as the patient with newly diagnosed dermatomyositis (for example, it is recommended that persons over 50 years of age should have a colonoscopy). Many authors have suggested that "blind" screening tests (beyond those mentioned

**Table 63.1** What is the risk of malignancy in patients with dermatomyositis or ADM?

First author, ref.	Population-based?	Patients with CA in the DM/ADM group	Patients with CA in the PM group	Statistically different?	Comment(s)
Sigurgeirsson [19]	Yes	59/392	37/396	Both groups had elevated rate vs controls. Cancer mortality raised only in DM	Ovarian cancer increased 17-fold Authors suggest increase in PM due to more extensive evaluation (diagnostic suspicion bias)
Airio [14]	Yes	19/71	12/175	SIR DM: 6.5 PM: 1.0	Risk rises with age, slight risk for overlap patients Nonmelanoma skin cancers, myelofibrosis, polycythemia vera, in-situ cervical cancer, and 12 preceding cancers eliminated Overrepresentation of ovarian cancer
Chow [16]	Yes	31/203	26/336	SIR DM: 3.8 PM: 1.7 reduced to 1.0 by 3rd year following diagnosis	Excess lymphoma/leukemia Surveillance for prolonged periods may not be needed
Hill [18]	Yes	115/618	95/914	SIR DM: 3.0 PM: 1.3	Plan for evaluation based on the results of their study suggested data derived from Swedish, Finnish, and Danish studies, but included additional follow-up from Denmark and Finland

First author, ref.	Population-based?	Patients with CA in DM/ADM group	Risk factor(s)	Effect (CA vs no CA group)	P/95% CI	Comments
Dourmishev [54]	No	12/50	Mean age	Higher in CA (59 y vs 49 y)	ND	No statistics available. Hospital-based study
			Poikiloderma	Pos (75% vs 32%)		
			Cutaneous ulceration	Pos (25% vs 2.7%)		
			Raynaud's	Neg (0% vs 17%)		
Nishikai [55]	No	12/36	Positive ANA	Neg (17% vs 54%)	<0.03	No data given on malignancies
Love [56]	No	13/92	Raynaud's	Neg (0% vs 40%)	ND	No statistics available. First study to link these protective effects into the "anti-synthetase syndrome"
			Arthritis	Neg (8% vs 55%)		
			Dyspnea	Neg (27% vs 59%)		
			ILD	Neg (0% vs 37%)		
			Positive ANA	Neg (31% vs 62%)		
			Anti-Ro/SSA	Neg (0% vs 11%)		
			Anti-U1RNP	Neg (0% vs 13%)		
			Anti-synthetase antibody	Neg (0% vs 33%)		
Trallero-Araguas [57]	No, cohort study	16/85 (PM and DM)	Anti-p155	Pos (OR of CA in DM, 23)	CI, 5.2–101	No statistical associations with peak CPK, dysphagia, ILD, or treatment response
			Shawl sign	Pos	$P < 0.01$	In DM, the PPV and NPV of anti-p155 for a diagnosis of CAM were 66.7% and 92%, respectively
Trallero-Araguas [58]	No, systematic review/meta-analysis	53/312	Anti-p155	Pos (OR of CA, 27.26)	CI, 6.59–112.82	In DM, the PPV and NPV of anti-p155 for a diagnosis of CAM were 58% and 95%, respectively
Hamaguchi [59]	No, multicenter cross-sectional	39/376	Anti-p155	Pos (10/17 with CA)	$P < 0.001$	Also found anti-CADM-140 to be associated with clinically ADM and rapidly progressive ILD
			Anti-Mi-2	Neg (0/9 with CA)	$P < 0.001$	Autoantibodies define distinct clinical subsets in DM and may be useful for predicting clinical outcomes
Fiorentino [62]	No	29/213	TIF-1 $\gamma$	Pos (OR, 1.6)	CI, 0.7–3.8; $P = 0.29$	Antibodies to either NXP-2 or TIF-1 $\gamma$ are present in most patients with cancer-associated dermatomyositis
			NXP-2	Pos (OR, 2.5)	CI, 0.9–6.7; $P = 0.069$	The absence of antibodies to either NXP-2 or TIF-1 $\gamma$ was strongly protective against cancer ( $P < 0.005$ )
			TIF-1 $\gamma$ or NXP-2	Pos (OR, 3.8)	CI, 1.3–10.8; $P = 0.013$	Stratification by sex showed that NXP-2 was specifically associated with malignancy in males (OR, 5.78; 95% CI, 1.35–24.7)

ADM, amyopathic dermatomyositis; ANA, antinuclear antibody; CA, cancer; CAM, cancer-associated myositis; CC, case-control; CI, confidence interval; PPV, positive predictive value; NPV, negative predictive value; CPK, creatine phosphokinase; DM, dermatomyositis; EMG, electromyography; ESR, erythrocyte sedimentation rate; ILD, interstitial lung disease; ND, no data; Neg, negative; OR, odds ratio; PM, polymyositis; Pos, positive; SIR, standardized incidence ratio.

above) are not fruitful in retrospective studies of patients with dermatomyositis [50,63–68].

On the other hand, other data support performing routine chest, abdomen, and pelvic computed tomography (CT) scans in adult patients presenting with dermatomyositis [18]. In one study, the positive result yield of a blind malignancy search was only 13%, but increased to 28% with blind chest/abdominal/pelvic CT scans [49]. The majority of these malignancies appeared to occur in patients experiencing cancer recurrence, suggesting increased surveillance in those with a known history of malignancy. In women, transvaginal pelvic ultrasound and mammography are also justified [49]. When comparing positron emission tomography/CT with conventional cancer screening (defined as chest and abdominal CT, mammography, pelvic ultrasound, gynecologic examination, and tumor marker analysis), the performances of both were comparable [69]. Another study demonstrated that sustained elevation of CA125 or CA19-9 are very specific findings in patients with cancer-associated dermatomyositis/polymyositis [70]. For patients with polymyositis, a chest radiograph and urinalysis should be performed at the time of diagnosis. Continued surveillance is necessary for patients with dermatomyositis for 3–5 years after diagnosis, but perhaps not for those with polymyositis [15,18,20]. However, what testing should be done beyond age-specific cancer screening remains somewhat unclear, and the clinician must formulate a plan in the absence of strong supporting data. Lastly, nasopharyngeal cancer is much more common among Asian patients in Southeast Asia, and a careful ear, nose, and throat evaluation is therefore warranted [29]. An additional study suggests that dermatomyositis patients residing outside of Southeast Asia, in areas such as the Mediterranean and North Africa, are also at increased risk of developing nasopharyngeal cancer, a risk not noted in Scandinavian and European studies on dermatomyositis-associated malignancies [71].

### Are there effective treatments for dermatomyositis?

The initial therapeutic approach to dermatomyositis depends on the presence of muscle and/or systemic disease. If present, systemic corticosteroids in relatively high doses are typically recommended as first-line therapy despite a lack of controlled studies supporting this approach. In addition, the early use of a corticosteroid-sparing agent is often proposed, with methotrexate, azathioprine, or mycophenolate mofetil being the most frequently suggested agents. In the absence of muscle and/or systemic involvement, there are no good data to support the use of systemic corticosteroids as a mainstay of therapy. Given that skin disease in dermatomyositis is often more refractory to treatment than the myositis, alternative agents are needed to avoid the side effects of systemic corticosteroids.

Do we know that these medications are effective, what the proper dosing should be, when a second-line agent should be introduced, which agent should be utilized, and what the likelihood of success is? Unfortunately, as is illustrated in Table 63.3 [36,72–119], the evidence available to answer these questions is poor. It is unclear whether the rate of remission is affected by systemic corticosteroids, whether they are used in high or low doses. In addition, there is little evidence regarding these therapeutic maneuvers for the treatment of cutaneous disease that might accompany dermatomyositis. Many reports do not specifically address skin disease response, and very few utilize the recently validated outcome measures for cutaneous disease.

Well-controlled randomized trials for this disease are lacking, and even the ones that have been conducted often lack power, or

have design flaws or potential biases. Many of the studies have included patients with cancer-associated myositis, a condition that is believed to respond less well than dermatomyositis without an associated malignancy. In addition, most studies mix dermatomyositis and polymyositis patients in their analyses, and it has become evident that these disorders differ in their pathogenesis and most likely have different responses to therapy.

### Current recommendations

It seems that there are no strong data that support the use of systemic corticosteroids in dermatomyositis, whether considering the muscle component, systemic disease such as pulmonary involvement, or the skin disease. Despite this lack of data, most authorities state that corticosteroids are a mainstay of therapy when myositis or systemic involvement is present. Therefore, it seems prudent to use corticosteroids for as short a period of time as is possible, substituting a steroid-sparing agent early in the course of treatment. Which of the agents to use is, in our view, dependent on the individual patient's co-morbidities and clinician's comfort level with the specific agent. For muscle disease, no high-quality trials support the use of a particular agent, with the possible exception of IVIG (see later). The addition of azathioprine to a corticosteroid regimen demonstrated a trend towards improvement [75]. Another study suggested that methotrexate and azathioprine do not appear to differ with respect to efficacy, although methotrexate was better tolerated [95].

Observations from individual case reports and small case series suggest that, for skin disease, hydroxychloroquine, methotrexate, and mycophenolate mofetil are effective corticosteroid-sparing agents. A retrospective series suggests that patients with dermatomyositis may have an increased risk of drug eruption to hydroxychloroquine [120]. Calcineurin inhibitors (such as ciclosporin and tacrolimus) also appear to be effective in skin disease, and may have a particular role.

IVIG has been the subject of a randomized controlled trial (RCT) and was found to be effective for both the muscle disease and the skin disease in patients with dermatomyositis refractory to corticosteroids and immunosuppressive agents. In this trial, 8 of 12 patients had “marked clearance” of skin disease as assessed through clinical photographs. Rituximab has recently been evaluated in an RCT; however, the primary outcome measure did not include any skin-specific measures, and no validated index to assess cutaneous disease response was utilized. Overall, the data regarding the use of rituximab specifically for cutaneous manifestations of dermatomyositis are limited.

What are the effects of treatments for juvenile dermatomyositis? This condition is complicated in two major ways. First, patients with juvenile dermatomyositis are more prone to calcinosis; and second, they may be permanently disabled by contractures. The results of retrospective case series suggest that the use of early “aggressive” therapy will limit the possibility of calcinosis [121,122]. Klein-Gitelman *et al.* [92] believe that high-dose intravenous pulsed methylprednisolone limits the risk and severity of calcinosis. However, adequate RCTs have not yet corroborated this belief. It does appear that, whatever the treatment, combination with physical therapy will prevent contractures from developing and that even if contractures occur, the use of physical therapy may improve the long-term disability. Once established, calcinosis may resolve spontaneously after a period of months to years; however, there are multiple individual case reports and some small series suggesting

Table 63.3 Treatments for patients with dermatomyositis.

First author (ref.)	Treatments compared/studied	Type of study	Outcome	Comments
<i>Corticosteroids</i>				
Winkelman [107]	CS therapy	Retrospective review of DM and PM  Primary end point: outcome of myositis	High-dose regimen (>50 mg/d) favored	No statistical analysis  Mixture of patients Identified some with an acute, fulminant course
Klein-Gitelman [92]	IVCS vs OCS	Retrospective comparison of 10	IVCS more costly, but more effective	Small group of patients
Bohan [36]	CS therapy	Retrospective of 124 patients	72% normalized CK levels	Mixture of patients
Nzeusseu [97]	Low-dose vs high-dose prednisolone (<0.5 vs >0.5 mg/kg/d)	Retrospective review of DM and PM ( $n = 25$ )	No difference in functional outcome	Vertebral fractures less common in low-dose group
Dawkins [81]	1 mg/kg/d prednisone with slow taper (over >2y)	Prospective DM (14 adult, 7 juvenile)	11/12 adults with normal strength/CPK 4/7 juveniles with normal strength/CPK	Cutaneous disease more difficult to treat
Van de Vlekkert [123]	High-dose pulsed oral dexamethasone vs daily high-dose prednisolone	Multicenter, double-blind RCT of patients with subacute onset myositis ( $n = 62$ ; 23 with DM)	No difference between treatment groups on composite score Side effects significantly less frequent in dexamethasone group	Mix of patients, fewer than half DM No statistically significant difference in skin changes on VAS (secondary outcome)
<i>Immunosuppressives</i>				
Mosca [96]	CS alone vs CS with immunosuppressive	Retrospective analysis	CS first-line therapy	
Bohan [36]	MTX for CS-resistant DM/PM Initial dose 10–15 mg/wk, raised to 30–60 mg/wk	Retrospective study. 25 patients (PM/DM)	16/25 improved strength	Minor, reversible toxicity
Ramanan [110]	CS alone vs CS with MTX	Retrospective study of juvenile DM	Addition of MTX resulted in decrease in total dose of CS, more rapid taper of CS. No difference in efficacy	Rapid CS taper only in MTX group, may have been tolerated in CS-only group
Bunch [75]	Prednisone 60 mg/d plus  AZA 2 mg/kg/d vs prednisone plus placebo	3-month DB-PC trial  16 patients with PM	No significant differences	
Miller [112]	CS+MTX vs CS+AZA	Double-blind, randomized ( $n = 28$ )	Equivalent efficacy on hand grip strength	MTX better tolerated than AZA
Villalba [104]	Oral weekly MTX and daily AZA vs i.v. MTX with leucovorin rescue	Randomized, open-label crossover study, 18 PM and 11 DM	ITT analysis showed trend in favor of oral combination	Toxicity slightly more common in i.v. group
Takada [101]	CYA (mean 156 mg/kg/d)	Retrospective analysis of 32 hospitals in Japan. 23 DM patients	Good response in 8/17 acute cases and 3/6 chronic cases	Only ILD measured as outcome. Unclear what parameters were measured
Kameda [90]	CYA (2–4 mg/kg/d) + CYT (10–30 mg/kg/d i.v.) + CS	Prospective study of 10 DM patients with severe ILD	5/10 survived. 5/10 died of respiratory failure	May compare favorably with historical controls (25% survival)
Heckmatt [88]	CYA (2.5–7.5 mg/kg/d)	Retrospective study of 14 patients with juvenile DM	Increased strength	
Danko [80]	CYA (2–3 mg/kg/d) (added to CS)	Retrospective of 10 DM patients, all refractory on CS $\pm$ AZA	“Remarkable” response in 6, “good” response in 4	Criteria for improvement unclear (muscle vs skin)
Maeda [111]	CYA	Retrospective study of 14 DM/PM patients in whom CS, MTX failed	9/14 “success” (still alive)	No mention of strength, skin response

Continued

Table 63.3 Continued

First author (ref.)	Treatments compared/studied	Type of study	Outcome	Comments
Grau [87]	CYA (5–10 mg/kg/d). No CS	Open-label study ( $n = 10$ ) 3 refractory, 7 new patients	Improvement in muscle function. Complete remission of skin disease in 9/10	Improvement more rapid than with historical CS + AZA. Oliguric renal failure in one patient. Only 10-month follow-up
Vencovsky [103]	CYA 3.0–3.5 mg/kg/d vs MTX 7.5–15.0 mg/wk with folic acid	Randomized, but not masked Mixture of PM and DM patients	Improvement equal. Trend towards superiority of MTX	Skin not evaluated
Wilkes [106]	Tacrolimus (0.075 mg/kg) b.i.d.	Retrospective study: 6 PM and 6 DM patients with interstitial lung disease	Significant improvement in strength and lung function	All had increased creatinine. Few with meaningful improvement in strength
Tausche [102]	MMF alone or with IVIG	Open-label, 4 patients	Three-quarters improved	One patient had cancer-associated DM
Majithia [94]	MMF+CS	Retrospective: 4 DM and 3 PM	Partial improvement of skin and muscle in all patients	One patient died of sepsis
Edge [82]	MMF alone or with other DMARD	Retrospective of 12 DM patients	Improvement of skin and strength in 10/12	1 recurrent breast cancer, 1 CNS lymphoma
Rowin [99] <sup>a</sup>	MMF+CS	Retrospective of 10 DM patients	Steroid-sparing in 6/7. Increased strength	3 opportunistic infections (1 patient died)
Riley [98]	I.v. CYT 0.5–1.0 mg/kg monthly alone or with DMARDs	Retrospective in 12 patients with refractory juvenile DM	10/10 response in muscle strength, 8/8 response in ulcerative skin disease	2 patients died. Significant infectious side effects. Response durable
Cronin [77]	I.v. CYT monthly	Retrospective ( $n = 6$ )	5/6 with “modest” improvement in strength	Serious infections (2) and death (11)
Sinoway [100]	Chlorambucil for DM	Open-label, 5 patients	Steroid-sparing	Assessment of myositis primarily
Adams [72]	Fludarabine 20 mg/m <sup>2</sup> for 3 d per month for 6 mos recalcitrant PM or DM	Open-label, 7 PM, 9 DM patients	Improved: 4 Unchanged: 7 Failures: 5	A subset of patients respond to this agent
<i>Plasmapheresis</i>				
Miller [95]	Plasma exchange or leukapheresis vs placebo	RCT of 39 patients with PM/DM	Equal effect to sham pheresis	Prior open-label trials had been positive
Cherin [76]	Plasma exchange	Retrospective, multicenter analysis of 24 PM and 33 DM patients in France	Significant improvement in acute myopathy only	PE given with albumin replacement in this study Must be combined with IVIG
Danieli [79]	CYA vs IVIG + CYA	Retrospective: PM ( $n = 8$ ) and DM ( $n = 12$ ). All on CS	Remission equal at 1 y, remission at 4 y more likely with CYA + IVIG	Combination well tolerated
Dalakas [78]	IVIG vs placebo for 3–6 months	DB-PC trial with crossover of 15	Statistically significant benefit for IVIG	Skin disease, strength, muscle biopsy
Al-Mayouf [73]	IVIG for JDM	Open-label, 18 JDM patients	Steroid-sparing	Small trial. Multiple regimens used
Gottfried [86]	IVIG for DM	Open-label trial with 19 patients (4 with cancer)	7 responders; nonresponders had severe skin and muscle disease, presence of MSA or cancer	IVIG monotherapy in some patients, used after immunosuppressive agents in some and with immunosuppressive agents in some
<i>Miscellaneous</i>				
Efthimiou [83]	Etanercept (+CS, IVIG)	Retrospective ( $n = 8$ ), PM and DM	6/7 patients improved with etanercept	1 splenic tumor. Only the nonresponder had a baseline normal CK
Muscle Study Group [124]	Etanercept plus prednisone vs prednisone alone (considered placebo group; each group was weaned off prednisone at a standardized schedule if tolerated)	Randomized, DB-PC pilot trial ( $n = 16$ ; 11 etanercept, 5 placebo)	No significant difference in adverse event rates Lower median average prednisone dose post week 24 in etanercept-treated group ( $P = 0.02$ )	5/11 etanercept-treated (vs 1/5 placebo-treated) developed worsening rash No significant difference in functional outcome

First author (ref.)	Treatments compared/studied	Type of study	Outcome	Comments
Dastmalchi [117]	Infliximab (5 mg/kg at weeks 0, 2, 6, and 14 × 4 mos)	Open-label trial (4 DM, 9 PM)	3/4 DM patients did not complete study (1 with severe erythema, 1 with worsening muscle disease, 1 with ovarian malignancy)	1 DM patient completed the study – did not improve based on muscle parameters
Hengstman [118]	Infliximab+MTX	Open-label trial (mixed DM and PM)	The few patients who reached the primary end point had improved muscle parameters	Terminated prematurely (low recruitment and high drop out from disease progression and infusion reactions)
Coyle [115]	Infliximab (5 mg/kg at weeks 0, 2, 6, and 14) vs placebo	Randomized, DB-PC trial with subsequent open-label crossover ( $n = 12$ ; only one with DM, 11 with PM)	7/12 on infliximab improved (vs 2/6 on placebo) Primary outcome met (improvement in MMT by 15% or more at 16wk)	Available in abstract form only Only one DM patient included
Levine [93]	Rituximab (375 mg/m <sup>2</sup> × 4) with or without other medication	Open-label in DM ( $n = 6$ )	All improved strength	4/6 relapsed with return of B cells Validated skin score not used
Chung [113]	Rituximab (1000 mg × 2)	Open-label in classic DM ( $n = 8$ ; 7 completed the study)	3/7 reached primary end point (at least 50% reduction in muscle deficit at week 24)	No improvement in skin scores using the validated DSSI
Oddis [114]	Rituximab (575 mg/m <sup>2</sup> for children with BSA ≤ 1.5 m <sup>2</sup> ; 750 mg/m <sup>2</sup> for patients with BSA > 1.5 m <sup>2</sup> , up to 1 g/infusion)	Multicenter RCT ( $n = 76$ DM, 76 PM, 48 JDM); randomized to: placebo at weeks 0, 1 and rituximab 1000 mg at weeks 8, 9; vs rituximab 1000 mg at weeks 0, 1 and placebo at weeks 8, 9	Did not reach primary end point (no difference in time to improvement in both groups) 161/195 (83%) had improvement in muscle disease Steroid-sparing effect was noted in both groups	The primary endpoint included 6 core measures of disease activity, none of which was skin specific No validated index to assess skin response was used
Wiesinger [105]	Physical training × 6 wk	Prospective, randomized study of 14 DM/PM patients	Improvement in muscle strength in treatment group	Suggests physical activity is safe for inflammatory myopathies
Takada [116]	Ecuzumab (humanized monoclonal Ab to CS) 8 mg/kg weekly × 5 wk followed by 2 × /wk for 2 additional doses vs placebo	Double-blind RCT ( $n = 13$ DM; 10 with ecuzumab, 3 with placebo)	No difference in adverse events MMT improved by 6% in treatment arm and 26% in placebo arm	Available in abstract form only
<i>Treatment of cutaneous disease of DM</i>				
Hollar [89]	Topical tacrolimus 0.1% ointment (all on CS±DMARD)	Open-label study ( $n = 6$ )	3/6 with acceptable improvement of rash	Not controlled
García-Doval [84]	Topical tacrolimus 0.1% ointment	Internally controlled (side-by-side comparison)	0/5 showed difference between treated and untreated sides	
Woo [108]	HCQ + CS (±MTX)	Retrospective ( $n = 7$ )	All patients had improvement of rash	No improvement in strength
Ang [74]	HCQ or CQ (±Q, ±DMARDs)	Retrospective ( $n = 17$ )	9/17 patients had “stabilization” of rash	Visual toxicity in 1 patient on CQ. Dyspigmentation in 3 on Q
Zieglschmid-Adams [109]	MTX for DM (7) or ADM (3), initial dose 7.5 or 9.2 mg/wk raised to 14.2 or 20 mg/wk for DM or ADM	Retrospective analysis	9/10 had improvement of skin disease	Mild, reversible toxicity in 7 patients Liver biopsy in 4 patients, 2 had hepatic fibrosis (grade IIIA)
Kasteler [91]	MTX for DM Eventual dose 2.5–30 mg/wk	Retrospective analysis 13 patients	CR – 4 PR – 9, steroid-sparing	Minimal toxicity
Hornung [119]	MTX for DM, dose 7.5–20 mg/wk	Retrospective analysis of 11 patients	8/11 with in skin disease (CDASI scores decreased from 15.7 to 6.4 ( $P < 0.01$ ) within 2–3 mos)	Responders had a more pronounced lymphocytic infiltrate in skin lesions
Gelber [85]	MMF for recalcitrant DM	Open-label, 4 patients	Steroid-sparing	

ADM, amyopathic dermatomyositis; AZA, azathioprine; CK, creatine kinase; CNS, central nervous system; CPK, creatine phosphokinase; CQ, chloroquine; CR, complete response; CS, corticosteroids; CYA, ciclosporin; CYT, cyclophosphamide; DB-PC, double-blind, placebo-controlled; DM, dermatomyositis; DMARD, disease-modifying anti-rheumatic drug; HCQ, hydroxychloroquine; i.v., intravenous; ILD, interstitial lung disease; ITT, intention-to-treat; IVCS, intravenous corticosteroids; IVIG, intravenous immunoglobulin; JDM, juvenile dermatomyositis; MMF, mycophenolate mofetil; MSA, myositis-specific antibodies; MTX, methotrexate; OCS, oral corticosteroids; PE, plasma exchange; PM, polymyositis; PR, partial response; Q, quinacrine; RCT, randomized controlled trial; VAS, visual analogue scale.

that various therapies – including warfarin, diltiazem, aluminum hydroxide, colchicine, minocycline, alendronate, pamidronate, probenecid, infliximab, IVIG, and hematopoietic stem cell transplantation – are variably effective in reversing the calcinosis. A multimodal approach to treating calcinosis is often warranted, including surgical excision of focal and disabling lesions.

## Background

Acquired subepidermal bullous diseases are a heterogeneous group of acquired blistering diseases. They may affect patients' skin and mucous membranes to different extents and can lead to scar formation. We conform to the disease definition of existing international consensus statements in this discussion of bullous pemphigoid (BP) and mucous membrane pemphigoid (MMP) [1,2]. BP is a non-scarring subepidermal blistering disease affecting mainly the skin; various autoantigens of the basement membrane zone (BMZ) mainly detected by immunoglobulin (Ig)G autoantibodies are recognized as being the targets. MMP is a (group of) subepidermal blistering disease(s) affecting mainly the mucous membranes, leading to scar formation in some patients. In MMP, various BMZ-antigens detected by IgG or IgA autoantibodies are associated with the disease. Autoantigens in the various acquired subepidermal bullous diseases may overlap considerably; this indicates that the autoantigen is not the only factor determining the clinical picture of the disease.

We will not discuss pemphigoid gestationis, a BP-like disease occurring in pregnancy; nor will we discuss linear IgA disease that shows considerable overlap with BP and MMP, considered as an entity by some because of the predominant IgA autoantibodies to various antigens and response to dapsone, or epidermolysis bullosa acquisita (EBA). All those "diseases" are very rare and show overlapping clinical as well as immunological features with BP and MMP [3–7].

## Bullous pemphigoid

### Definition

BP is an acquired non-scarring autoimmune subepidermal bullous disease characterized by tense blisters. Circulating IgG autoantibodies (rarely IgA, IgM, and IgE) typically bind to BP230 and BP180 (collagen XVII) antigens, which are components of the hemidesmosomal adhesion complex found in the BMZ of the skin. Direct antibody–antigen interaction, local activation of complement and release of cytokines lead to loss of dermoepidermal

adherence and formation of subepidermal blisters [8]. Blistering typically occurs in flexural sites although BP may be generalized or localized to one site such as the lower legs. Erosions and blisters occur on the mucous membranes, particularly the mouth, in about 50% of cases; however, they are usually not troublesome for the patient. Blister formation may be preceded for many months by pruritus, urticarial or eczematous rashes (Figure 64.1).

### Incidence/prevalence

BP is the most common autoimmune blistering disease in the West. In the UK [9], the reported incidence is 43 per million per year and 7–13 per million per year in other parts of Europe [10–12]. The mean age of onset is around 80 years. According to a Scottish study, there is no sex preponderance [13].

### Etiology

No clear etiological factors have been identified. There are anecdotal reports of BP being preceded by local cutaneous trauma. There is an association between BP and certain neurological diseases, such as cerebrovascular disease, dementia, and possibly Parkinson's disease, epilepsy, and multiple sclerosis [14–19]. BP is possibly triggered by drugs in certain patients [20]. There does not seem to be an increased risk of malignancy or other autoimmune diseases in patients with BP in Western countries compared with controls [13,21].

### Prognosis

BP is usually a self-limiting disease with a clinical course that may last from months to years. The majority of patients with BP will have disease remission within 5 years [22]. During the active stage, the disease is associated with significant morbidity and a mortality twice that of the general elderly population [9]. Older age at onset and frail general condition are poor prognostic factors. The mortality rate seems to be highest within the first 2 years of diagnosis [13,23]; according to the Scottish study, 48% died within 2 years (unrelated and related to BP or treatment); respiratory disease accounted for a higher than expected number of deaths [13]. Mortality during the first year is significantly higher in patients

Figure 64.1 Crusted erosions and large hemorrhagic bullae.

treated with high doses of systemic corticosteroids (prednisolone equivalent  $>40$  mg/day) [24]. Treatment should aim to control symptoms with minimum adverse effects where possible, as both treated and untreated BP shows a chronic relapsing course. Options are broadly divided into anti-inflammatory drugs, immunosuppressive or immunomodulating drugs, and procedures aiming to remove circulating pathogenic antibodies and inflammatory mediators.

### Aims of treatment

The aims of treatment are to achieve quick healing of skin and mucous membrane lesions and to improve quality of life with minimal adverse effects. The choice of treatment depends on an individual patient's circumstances, especially the severity and presence of co-morbidities

### Outcomes

- Rate of healing of blisters and suppression of new blister formation.
- Effect on quality of life.
- Duration of remission whilst on treatment and after cessation of treatment.
- Complications of disease.
- Adverse effects of treatment, including mortality.

### Methods of search

Randomized controlled trials (RCTs) were identified from searches of Skin Group Specialised Register, the Cochrane Central Register of Controlled Trials, Medline, and Embase up to July 2012. All RCTs on interventions for BP confirmed by immunofluorescence studies were included.

A systematic review [25] of treatments for BP identified 10 RCTs, with a total of 1049 patients and nine ongoing trials: ACTRN12607000104459 (rituximab), NCT00286325 (rituximab), NCT00472030 (omalizumab), NCT00525616 (rituximab (Mabthéra)), NCT00802243 (leflunomide), NCT01571895 (Oral DF2156A), NCT00809822 and NCT01408550 (NPB-01 (intravenous Ig)), and ISRCTN13704604 (doxycycline versus prednisolone); the latter three are ongoing RCTs.

Detailed data on a completed 11th RCT comparing dapsone versus systemic steroid treatment in BP are not available [26].

## Questions

### What are the effects of systemic corticosteroids?

#### Benefits

Two small RCTs looked at the effects of systemic corticosteroids alone [27,28]. Dreno *et al.* compared biologically equivalent dosages of different corticosteroids: methylprednisolone, 1.17 mg/kg per day, and prednisolone methylsulphobenzoate, 1.16 mg/kg per day [27]. Morel and Guillaume compared different dosages of prednisolone: 0.75 mg/kg per day with 1.25 mg/kg per day [28]. Both trials found no statistical difference in effectiveness of treatment.

#### Harms

Higher doses of prednisolone were associated with more side effects, including infection, hepatic and renal impairment, cerebrovascular accident, hypertension, heart failure, and death.

#### Comment

Systemic corticosteroids are considered standard treatment for BP, although a placebo-controlled trial has not been carried out. Higher doses of corticosteroids are associated with increased morbidity and mortality.

### What are the effects of topical corticosteroids?

#### Benefits

We found two RCTs comparing very potent topical steroids versus prednisone [29,30].

In the first study [29], 341 patients with BP were stratified according to disease severity: moderate ( $\leq 10$  new blisters per day) or extensive ( $>10$  new blisters per day). Patients were randomly assigned to receive either topical clobetasol propionate cream (40 g b.i.d.) or oral prednisone (0.5 mg/kg per day for moderate disease and 1 mg/kg per day per for extensive disease). In the extensive disease group, those using topical steroids had a better survival rate at 1 year compared with those on oral steroids (76% vs 58%). This was consistent with the incidence of severe complications in the two extensive disease groups (29% for topical steroids vs 54% for oral steroids). The disease was controlled in 99% of the patients using topical steroids versus 91% of those on oral steroids at 3 weeks. In the moderate disease group, no significant differences were seen between the topical steroid and 0.5 mg/kg oral steroid groups in terms of overall survival, rate of disease control at 3 weeks, or the incidence of severe complications. In conclusion, disease control was similar comparing topical steroids with 1 mg/kg prednisone in the extensive group and 0.5 mg/kg prednisone in the moderate group. However, severe adverse effects and mortality were nearly double with 1 mg/kg prednisone compared with topical steroids; there was no difference with 0.5 mg/kg prednisone.

A second trial [30] investigated two different regimens of topical clobetasol propionate cream: 40 g cream per day versus a mild regimen of 10–30 g/day, depending on the body weight and severity of the disease. For moderate disease ( $\leq 10$  new blisters per day): 69 participants received 20 g/day if their body weight was  $\geq 45$  kg and 10 g/day if  $<45$  kg. For severe disease ( $>10$  new blisters per day): 90 participants received 30 g/day if their body weight was  $\geq 45$  kg and 20 g/day if  $<45$  kg. In the standard regimen, all participants received 40 g of the cream per day (moderate disease,  $n = 65$ ; severe disease,  $n = 88$ ).

In the mild regimen, 156/159 participants were controlled by day 21, and 150/153 in the standard regimen, which is not statistically significant; disease severity did not influence the results. There was

a 70% reduction in cumulative doses of corticosteroid used in the mild regimen. Eighty-nine patients in each group had severe adverse events; these were diabetes mellitus (34 vs 18), cardiovascular and neurovascular (35 vs 21), and severe infections (32 vs 27) in the standard and mild regimen groups respectively. There were also cutaneous side effects. In the mild regimen, 60/159 participants had died by year 1 (moderate disease, 19/69; severe disease, 41/90) and 58/153 in the standard regimen (moderate disease, 21/65; severe disease, 37/88). This was not statistically significant. However, an adjusted analysis (Cox model adjusted for age and Karnovsky score) showed a strong beneficial effect of the mild regimen in patients with moderate disease with an almost twofold reduction in death or life-threatening side effects, as compared with those treated with the standard regimen. In conclusion, the mild regimen was associated with less adverse effects over time.

### Harms

Skin infection, skin atrophy, and evidence of systemic absorption may be seen. There is a high risk of severe adverse reaction and death with 1 mg/kg per day prednisone.

### Comment

The two RCTs suggest the use of topical steroids as first-line for the treatment for both localized and mild disease [29,30]. Relatively few and mild side effects are associated with topical corticosteroid treatment in BP; however, their use in extensive disease may be limited by more side effects and practical factors (e.g., need for nursing input). Evidence suggests that 0.5 mg prednisone per kilogram per day is an appropriate dose for severe BP.

## Does combination treatment offer any advantage over corticosteroid monotherapy?

### Benefits

We found four nonblinded RCTs [31–34]. Burton *et al.* compared prednisolone, 30–80 mg/day, alone and in combination with azathioprine, 2.5 mg/kg per day. The addition of azathioprine resulted in a 45% reduction in prednisolone dose over a 3-year period [31]. Roujeau *et al.* compared prednisolone, 0.3 mg/kg per day, alone and in combination with plasma exchange. They found that less than half the total prednisolone dose was required in the plasma exchange group [32]. Disease control was achieved within weeks in both groups – in the plasma exchange group with a mean plus/minus standard deviation prednisolone dosage of  $0.52 \pm 0.28$  mg/kg per day and in the prednisolone-only group with  $0.97 \pm 0.33$  mg/kg per day. Guillaume *et al.* compared prednisolone 1 mg/kg per day alone or in combination with either azathioprine (100 mg for body weight <60 kg and 150 mg for body weight >60 kg) or plasma exchange [33]. This trial failed to confirm any benefit of combination therapy over prednisolone alone. Beissert *et al.* compared azathioprine (2.0 g/kg per day) to mycophenolate mofetil (1 g b.i.d.) as adjuncts to methylprednisolone (0.5 mg/kg per day). Remission was achieved in 100% of patients in both groups, but this trial included no steroid-only arm, so no conclusions can be drawn as to superiority of either adjunctive treatment over steroids alone [34]. Azathioprine was slightly faster to produce remission than mycophenolate (median 28.6 days compared with 42 days); however, relapse rates were similar. Finally, a small trial compared 15 patients with traditional Chinese medicine, “Jingui Shenqi Pill,” plus prednisone (0.5–1.0 mg/kg per day) with 15 patients on prednisone only (0.5–1.0 mg/kg per day) [35]. At 4 weeks, complete healing was achieved in one participant receiving the Jingui Shenqi

Pill and none in the prednisone group. Partial healing was achieved in 13 of 15 with Jingui Shenqi Pill treatment compared with 11 of 15 participants with prednisone-only treatment. None of the results were statistically significant.

### Harms

The addition of azathioprine and/or plasma exchange did not increase the incidence of side-effects; in fact, similar side-effect profiles were seen in the studies of Burton *et al.* and Roujeau *et al.* [31,32]. Guillaume *et al.* commented that most side effects could be attributed to corticosteroids, but details were not supplied [33]. Beissert *et al.* found a similar incidence of side effects with azathioprine and mycophenolate. Hepatotoxicity was documented in 6/37 patients treated with azathioprine, but more infections occurred with mycophenolate mofetil (MMF) [34].

### Comment

With the current available evidence the value of combination treatment remains doubtful.

## Are non-antibiotic properties of antimicrobials useful?

### Benefits

One small RCT compared prednisolone, 40–80 mg/day, with tetracycline, 2 g/day in four divided doses, plus nicotinamide, 1500 mg/day in three divided doses [36]. This trial suggested no statistically significant difference in treatment response.

### Harms

More serious side-effects (including death due to sepsis) were noted in the prednisolone group. One patient with established renal impairment in the tetracycline/nicotinamide group developed acute tubular necrosis; however, concomitant medications included aspirin and ibuprofen.

### Comments

This was a small trial of 18 patients, with an unclear method of randomization and a high drop-out rate.

An ongoing RCT (ISRCTN13704604) is investigating the effectiveness of doxycycline 200 mg/day versus prednisolone 0.5 mg/day in 256 patients (<http://www.controlled-trials.com/ISRCTN13704604>). The primary outcomes are effectiveness measured by a blinded blister count at week 6 and safety at 1 year; results are expected by October 2014.

Dapsone was compared with azathioprine in a small RCT of 54 patients with BP; 27 patients received methylprednisolone 0.5 mg/kg per day plus azathioprine 1.5–2.5 g/kg per day versus 27 patients receiving methylprednisolone 0.5 mg/kg per day plus dapsone 1.5 mg/kg. Preliminary results are presented; the main result was an earlier effect on healing of lesions in the dapsone group after 2.8 months versus 6 months in the azathioprine group; final results are awaited [26].

## What are the effects of immunoglobulins?

In studies NCT00809822 and NCT01408550, NPB-01 (intravenous Ig) therapy is compared with physiological saline for patients unresponsive to corticosteroids. Primary outcome measures are skin lesion area (percent), number of new blisters/day, pemphigoid activity score, anti-BP180 and -BP230 antibody titers, and steroid dose. These are randomized double-blind, placebo-controlled,

parallel assignment phase II and phase III studies. Data are not available.

### What are the effects of monoclonal antibodies?

Monoclonal antibody therapies could offer alternatives to long-term steroid use, or may permit the dose of steroids or immune-suppressive drugs to be reduced. Four of the ongoing studies are investigating the use of such biological agents. The use of rituximab as an adjuvant treatment in BP is being studied in ACTRN12607000104459, and the efficacy and tolerability of a single cycle of rituximab in the control of BP is being examined in NCT00525616. The safety and efficacy of omalizumab is being tested in NCT00472030, and the safety of treatment of BP in participants resistant to therapy with systemic corticosteroids, with rituximab plus systemic corticosteroids, in NCT00286325. Monoclonal antibody therapy may have a role to play in treatment of BP; however, it is not without adverse reactions, including infusion reactions, fever, neutropenia, chills, increased risk of infection, weakness, and fatigue.

#### Key points

- Few RCTs on systematic review of treatments for BP were identified.
- The available evidence is inadequate to allow confident recommendation of optimal treatment.
- Systemic steroids are the best established treatment for BP.
- Immunosuppressive and metabolic adverse effects occur and are dose dependent.
- Therefore, a less aggressive approach to therapy with low doses of corticosteroids may be sufficient for disease control and appears to be associated with less morbidity and mortality.
- Very potent topical steroids (clobetasol propionate) are an effective treatment for BP. They seem to have less serious adverse effects compared with 1 mg/kg of prednisone per day. However, their use in extensive disease may be limited by practical factors, and they may be associated with systemic absorption and adverse events. When feasible they should be considered for first-line treatment, especially in localized disease.
- Tetracyclines and nicotinamide may be effective; data of an ongoing, larger trial comparing doxycycline with prednisolone are expected late in 2014; this may clarify the effect on the anti-inflammatory effect of tetracyclines.
- The benefits of azathioprine, MMF, and plasma exchange are difficult to assess.

Strength of recommendation B.

## Mucous membrane pemphigoid

### Background

#### Definition

MMP is an acquired autoimmune bullous disease affecting primarily the mucous membranes and to a lesser extent the skin [2]. Following the international consensus in 2002, some patients previously considered to be linear IgA disease or EBA were reclassified as MMP (formerly cicatricial pemphigoid). Autoantibodies are directed against constituents of the hemidesmosomal adhesion complex of the skin and mucous membranes; the main autoantigens are BP180 and laminin-332 (laminin 5), and less commonly the  $\alpha 4$  and  $\beta 6$  integrins, collagen VII and other antigens. Autoantibody–autoantigen interaction leads to blister formation [2,37–39]. Direct immunofluorescence investigation of patients' skin or mucosa shows linear IgG, IgA, and C3 deposits at the der-

moepidermal junction, and indirect immunofluorescence of patients' serum may reveal circulating autoantibodies. Indirect immunofluorescence using salt-split skin may show binding to the roof (epidermis) in BP180-MMP or to the floor (dermis) in laminin 332-MMP of the artificial blister [38,39]. Scar formation is characteristic at many sites, though less commonly seen in the oral mucosa, and may result in blindness and respiratory obstruction.

### Incidence/prevalence

The incidence of MMP is estimated at 0.87 cases per million population per year in western Europe [40]. There is a slight female preponderance (1.5:1), and the elderly are more commonly affected.

### Etiology

The etiology is unknown; there are reports of drug-induced MMP [41].

### Prognosis

The course of MMP is variable; usually it is a very chronic disease [2]. Presentation may vary from stable oral involvement to rapidly progressive ocular disease despite immunosuppressive therapy.

### Aims of treatment

The aims of treatment are to achieve quick healing of mucosal and skin lesions, prevent scarring in the longer term induce disease remission, and to improve quality of life with minimal adverse effects.

### Relevant outcomes

- Rate of healing of blisters, cessation of blistering, and prevention of scarring.
- Effect on quality of life.
- Duration of remission after cessation of treatment.
- Complications of primary disease.
- Adverse effects of treatment, including mortality.

### Methods of search

RCTs of patients with MMP were identified from Medline/PubMed and Embase from their inception to July 2012. The Cochrane Skin Group Specialised (CSG) Register, the Cochrane Controlled Trials Register (CCTR: CENTRAL), [www.controlled-trials.com](http://www.controlled-trials.com), and [www.clinicaltrials.gov](http://www.clinicaltrials.gov) were last examined in August 2012. The bibliographies from identified studies were searched. However, because MMP is a rare disease we did not expect to find many RCTs and, therefore, also considered evidence from nonrandomized studies and case reports with diagnoses confirmed by immunofluorescence studies.

There is one systematic review of therapeutic interventions for MMP [42]. That review identified two small RCTs by Foster for the treatment of ocular MMP, but there were no placebo-controlled trials [43]. We identified one further RCT [44] and two ongoing trials.

## Questions

### What are the effects of combination therapy with cyclophosphamide?

#### Benefits

#### *Cyclophosphamide plus prednisolone versus prednisolone*

One double-blind RCT included 24 patients with bilateral ocular, stage III MMP (symblepharon formation). It compared pred-

nisolone (initially 1 mg/kg per day) alone versus cyclophosphamide (2 mg/kg per day) plus prednisolone [43, pp. 619–38, published data only]. Cyclophosphamide in combination with prednisolone was found to be effective in removing evidence of bilateral inflammation in stage III eye MMP in 12/12 participants. Only 5/12 participants had achieved disease control in the prednisolone-only group, and in all a recurrence of conjunctival inflammation occurred on tapering treatment (relative risk, 2.40; 95% confidence interval, 1.23–4.69).

#### ***Cyclophosphamide versus dapsone***

A second RCT included 40 patients with stage III ocular MMP [43, pp. 638–40, published and unpublished data]. It compared dapsone (2 mg/kg per day) with cyclophosphamide (2 mg/kg per day) in 40 patients with stage III ocular MMP. It is not clear, but both groups most likely had additional prednisolone, as in the above-mentioned trial [43, pp. 619–38, published data only]. Cyclophosphamide was found to be superior to dapsone in resolving severe inflammation of the eyes (20/20 vs 14/20; relative risk, 1.43; 95% confidence interval, 1.07–1.90). All six patients who did not improve after 3 months of dapsone treatment responded to cyclophosphamide.

#### **Harms**

No patients withdrew from systemic immunosuppression because of adverse effects. All of the patients in the prednisolone group experienced steroid-related adverse effects. Leukopenia was a routine finding in patients treated with cyclophosphamide; the dose was adjusted to achieve a white cell count of 2500–4000/ $\mu$ L; reversible hair loss and asymptomatic macrocytic anemia were common findings. Routine urinalysis detected microcytic hematuria in about 10% of patients taking cyclophosphamide. An alteration in timing of cyclophosphamide administration and increased fluid intake eliminated this potentially serious side effect (hemorrhagic cystitis). Male sterility may occur; there is a potential for development of malignancies (DNA damage).

#### **Comments**

With careful monitoring, systemic cyclophosphamide may pose fewer risks than long-term corticosteroid therapy for moderate and severe disease.

#### **What are the effects of sulfa-drugs?**

##### **Benefits**

There are no RCTs comparing the different sulfa-drugs. A small observational study (20 patients) describes that sulfapyridine may be superior to dapsone in moderate ocular MMP [45]. Another study suggests that sulfasalazine is effective in maintaining disease control in 6/9 patients with ocular MMP who have had previous dapsone-related side effects, although 2/6 required additional oral cyclophosphamide [46].

##### **Harms**

Dapsone must be given with care to patients with glucose-6-phosphate-dehydrogenase deficiency; some degree of anemia is common in most patients. There are potentially serious adverse effects in treatment with dapsone, like severe hemolytic anaemia, methemoglobinemia, agranulocytosis, neuropathy, and the dapsone syndrome (rash with fever and eosinophilia), which requires the immediate cessation of dapsone, because it may progress to exfoliative dermatitis and death.

#### **Comments**

Dapsone appears to be a reasonable first choice in patients with little inflammation and slowly progressive disease (the dose needs adjusting in glucose-6-phosphate dehydrogenase deficiency).

#### **Are non-antibiotic properties of antimicrobials useful?**

##### **Benefits**

Small noncontrolled studies (total of 25 patients) [47,48] indicate that minocycline (50–100 mg/day) or tetracycline (1 g/day) combined with nicotinamide (2.5–3 g/day) may be beneficial in oral disease.

##### **Harms**

Hyperpigmentation is a common side effect with minocycline.

##### **Comments**

RCTs are required to confirm the benefit of non-antibiotic properties of antimicrobials.

#### **What is the effect of intravenous immunoglobulin?**

##### **Benefits**

The use of intravenous Ig (IVIg) is described in one noncomparative case series of 10 patients with treatment-resistant progressive ocular MMP and showed resolution of conjunctivitis after 4–12 cycles of IVIg treatment (2–3 g/kg body weight per cycle every 2–6 weeks) [49]. A nonrandomized comparison between conventional immunosuppressive and IVIg therapies investigated eight patients in each group [50]. All patients received (various) immunosuppressive treatment as an initial treatment before treatment with IVIg.

##### **Harms**

There were no untoward side effects in these case series.

##### **Comment**

Comparative studies are needed. IVIg therapy is expensive [51].

#### **What is the effect of mycophenolate mofetil?**

##### **Benefits**

In a case series, treatment with MMF achieved complete control of inflammation in 70% of 18 treated patients with ocular pemphigoid (7% of a large cohort of different ocular inflammatory diseases) by 1 year [52]. In a series of 115 patients with ocular pemphigoid, patients were treated with various immunosuppressive drugs; cyclophosphamide therapy was more successful (69% success) than MMF (59% success) [53].

##### **Harms**

Lack of appetite, nausea, and mild diarrhea were common early side effects. Severe side effects resulting from immunosuppression were not noted in these series. In both studies, MMF had the least side effects among the immunosuppressive drugs used.

##### **Comment**

Larger comparative studies are needed to assess treatment efficacy of MMF.

#### **What is the effect of pentoxifylline?**

##### **Benefits**

The cytokine tumor-necrosis factor (TNF) has been detected in inflamed conjunctiva of MMP patients. The anti-inflammatory

(anti-TNF $\alpha$ ) effect of pentoxifylline was tested in 30 patients with ocular MMP [44]. Pulse steroids combined with cyclophosphamide in group A and intravenous pentoxifylline added to the combination in group B. Histopathological features and serum levels of TNF improved significantly. There were 0/9 relapses in group B after 18-month follow-up but 4/7 in group A.

## What is the effect of biologics?

### Benefits

Treatment with “biologics,” like TNF alpha receptor blocker (etanercept), infliximab, and anti-CD25 (daclizumab) which is now withdrawn, have been described in case reports. There are individual case reports and a small series of 25 patients with severe refractory MMP treated with anti-CD20 (rituximab). The series reported a response rate of 88%, with some patients requiring a second cycle to achieve remission [54].

### Harms

Severe side effects, including death, occurred in two patients when used concomitantly with glucocorticoids and immunosuppression.

### Comment

Further studies are needed.

### Ongoing trials

#### ISRCTN54055321: ex vivo expanded corneal limbal stem cell transplantation

This is a pilot clinical assessment of ex vivo expanded corneal limbal stem cell transplantation in patients with severe ocular surface diseases arising from limbal stem cell deficiency.

#### ISRCTN51714283: a randomized controlled trial of pulsed intravenous methylprednisolone for severe ocular pemphigoid

This tests the hypothesis that intravenous methylprednisolone induces more rapid control of ocular inflammation in patients with severe ocular pemphigoid.

### Key points

- The available evidence is inadequate for confident recommendation of optimal treatment.
  - Dapsone combined with systemic corticosteroids may be helpful in the management of mild ocular MMP with modest inflammation.
  - Cyclophosphamide combined with systemic corticosteroids appears to suppress inflammation and scarring in moderate to severe ocular MMP.
  - Antimicrobials, MMF, IVIGs, and rituximab are of unknown benefit in the management of MMP. RCTs are needed to determine their efficacy.
- Strength of recommendation B

## Background

### Definition

Pemphigus is an intra-epidermal autoimmune blistering disease involving the skin and mucous membranes. Pemphigus is conventionally divided into three distinct subtypes: pemphigus vulgaris, pemphigus foliaceus, and paraneoplastic pemphigus. Pemphigus vulgaris is characterized by blisters affecting both oral and cutaneous surfaces, whereas patients with pemphigus foliaceus have only cutaneous involvement (Figure 65.1). Patients with paraneoplastic pemphigus have striking mucous membrane disease, as well as a polymorphous skin eruption, with a poor prognosis. In this chapter we will exclusively address pemphigus vulgaris and foliaceus.

### Epidemiology

The incidence of pemphigus has been estimated at approximately 1 in 1 000 000 to 1 in 100 000 per year, depending on the population in question [1].

### Etiology

As is the case with other autoimmune diseases, the exact pathophysiological mechanism that causes immune dysregulation in pemphigus is unknown. Pemphigus is a T-cell-driven autoantibody-mediated disease, with T cells reacting to specific antigenic adhesion proteins in the skin. The production of autoantibodies to intercellular proteins in the epidermis, along with various inflammatory mediators, is believed to directly elicit acantholysis. The clinical phenotype of pemphigus is defined by the specific profile of autoantibodies. Patients with mucosal-dominant pemphigus vulgaris have only antidesmoglein 3 immunoglobulin (Ig)G autoantibodies. Patients with mucocutaneous pemphigus vulgaris have both antidesmoglein 3 and antidesmoglein 1 autoantibodies. Patients with pemphigus foliaceus, who have only skin lesions, have antidesmoglein 1 antibodies [1].

### Prognosis

The mortality of pemphigus decreased dramatically after corticosteroids were introduced as therapy in the 1950s. Before that time, the mortality was approximately 70% and usually resulted from sepsis [2]. With corticosteroids and adjuvant therapy, the mortality is now approximately 6%, with most deaths being related to side effects of therapy [3].

### Diagnosis

Diagnosis is based on four measures:

- *Clinical features:* oral ulcers, flaccid blisters, or erosions with scale.
- *Histological features:* acantholysis with loss of coherence between epidermal cells.
- *Immunofluorescence:* detection of autoantibodies either in a biopsy specimen (direct) or in the patient's serum (indirect) in an intercellular pattern with IgG and C3.
- *The enzyme-linked immunosorbent assay:* antidesmoglein 1 or 3 antibodies – antibody titers may correlate with disease activity [4].

### Aims of treatment

The main aims of treatment in pemphigus are to suppress new blister formation and promote the healing of old lesions whilst minimizing the side effects of treatment.

### Relevant outcomes

Interpretation of evidence is complicated by the lack of uniform outcome measures. Outcomes regarding disease control include prevention of new blister formation, healing of old lesions, and the time required to achieve disease control. In the longer term, the proportion of patients able to discontinue treatment and the proportion of patients who relapse are important. The safety of treat-

**Figure 65.1** Patient with extensive erosions and flaccid bullae due to pemphigus vulgaris.

ments is especially important, as the major morbidity is derived from complications of treatment. Cumulative steroid dose is often measured as a surrogate for steroid-induced adverse events. Autoantibody titers are reported to correlate with disease activity. Patient-based measures, including quality of life, should also be considered. An international consensus document regarding relevant outcomes and definitions of response has been published [5]. Two validated severity scores have also now been published, which will aid meta-analysis in the future [6,7].

### Search strategy

Articles were identified from the Cochrane Central Register of Controlled Trials (Central), Medline, and Embase, using the Cochrane Collaboration's highly sensitive search strategy.

### Study selection criteria

We focused our analysis on randomized controlled trials (RCTs), but also included nonrandomized trials and large case series when RCTs were lacking.

## Questions

### What is the optimal dosing strategy for corticosteroids in newly diagnosed patients?

Corticosteroids are firmly established as the mainstay of treatment for pemphigus. Their introduction in the 1950s was associated with a dramatic decrease in mortality [8–10]. Initially, very high doses were employed, but these doses were associated with significant adverse events, and the rationale for high-dose regimens has been questioned [11–13].

In the only RCT to address steroid-dosing regimens, Ratnam *et al.* compared the efficacy of different prednisolone doses [14]. Twenty-two previously untreated patients with severe disease (>50% of the body surface area affected) were randomly assigned to “high-dose” (120–150 mg/day;  $n = 11$ ) or “low-dose” (30–60 mg/day;  $n = 11$ ) prednisolone. Patients also received adjuvant therapy with methotrexate or cyclophosphamide when steroids were tapered below 20 mg/day. Patients were followed for 5 years. All patients were seronegative for pemphigus autoantibodies after 3

months of treatment (initial titers ranged from 1:40 to 1:160). All patients in both groups had resolution of blister formation. There was no difference between the duration of prednisolone therapy required to control disease (average 19 vs 24 days). There was no difference in the number of relapses between groups, or in the time to relapse. Steroid-related complications occurred in both groups, with a trend towards more complications in the high-dose group. Therefore, this trial suggested that a “high-dose” regimen offered no advantage over a “low-dose” regimen.

Fernandes and Perez reported a nonrandomized controlled trial involving 71 patients (41 with pemphigus vulgaris, 30 with pemphigus foliaceus) [15]. Patients were allocated to groups receiving 1 mg/kg per day ( $n = 34$ ) or 2 mg/kg per day ( $n = 37$ ) prednisone, according to baseline disease severity. No adjuvant agents were given, and steroids were tapered after 4–6 weeks. Patients were followed for 5 years. Suppression of blister formation was similar in the two groups, with 24 of 34 patients on low-dose treatment and 27 of 37 patients on high-dose treatment responding to therapy. Two patients in the low-dose group and four in the high-dose group died. There was a significant difference in the number of adverse events, in particular infection, with 16 infections reported in the low-dose group and 48 in the high-dose group. Although the lack of randomization in this study detracts from the validity of the results, it suggests that high doses of steroid are no more effective and are associated with higher morbidity.

In summary, the evidence indicates that lower dosage steroid regimens ( $\leq 1$  mg/kg per day) have equivalent efficacy in inducing disease control and that higher dosage regimens are associated with increased morbidity.

### Does pulsed corticosteroid therapy increase efficacy or reduce morbidity?

Pulsed therapy is based on the rationale that short-term high-dose steroid may achieve more rapid control of disease and decrease cumulative steroid dose, thus reducing complications resulting from long-term usage. There has been one RCT, one nonrandomized controlled trial, and four case series reporting on the use of pulsed corticosteroid therapy.

Mentink *et al.* reported an RCT including 20 pemphigus vulgaris patients with new disease or new disease activity randomized to oral dexamethasone 300 mg pulses 3 days per month ( $n = 11$ ) or placebo ( $n = 9$ ) [16]. Both treatment groups also received prednisolone 80 mg/day, tapered over 19 weeks, and azathioprine 3 mg/kg per day. Monthly pulses were continued until prednisolone was tapered to zero, and the patients were followed for 1 year. Eight of the 11 patients with pulsed dexamethasone and all nine of the patients on placebo were able to discontinue all steroids. There were no differences in the time to remission, duration of remission, or relapse rate. The mean cumulative steroid dose was higher in the pulsed group. Adverse events occurred more commonly in the pulsed group, and three of nine patients withdrew due to side effects. Adverse events with pulsed therapy included viral hepatitis, muscle weakness, cognitive problems, and weight gain.

Femiano *et al.* reported an open nonrandomized controlled trial of 20 patients with new-onset pemphigus vulgaris [17]. The patients were treated with a tapering schedule of prednisone 125 mg/day ( $n = 10$ ) or intravenous betamethasone 20 mg/day for 4 days/month and prednisone 50 mg/day. There was no difference in the time to achieve disease control (30 vs 25 days). Adverse events were reported less commonly in the pulsed group.

A study of pulsed dexamethasone and cyclophosphamide versus pulsed cyclophosphamide and prednisolone, discussed later, also did not demonstrate a benefit for pulsed dexamethasone [18].

These controlled trials did not demonstrate an additional benefit for pulsed corticosteroids, and were associated with more severe side effects. However, patients in these controlled trials were predominantly newly diagnosed, and as pemphigus is steroid responsive overall, a difference would not be expected without selection for a subgroup of patients with severe or refractory disease. The role for pulsed corticosteroid therapy in patients with severe or refractory disease is not clear.

### **Are immunosuppressive drugs (azathioprine, cyclosporine, cyclophosphamide, methotrexate, mycophenolate) in addition to corticosteroids beneficial in improving efficacy or reducing morbidity?**

Immunosuppressive medications are widely used owing to their theoretical advantage of improving efficacy while reducing steroid-induced complications. These agents are slow acting, so their primary role is in maintenance therapy rather than in inducing remission. There have been seven RCTs of immunosuppressants, including a four-arm trial comparing prednisolone alone versus adjuvant azathioprine, cyclophosphamide, and mycophenolate mofetil in 120 patients [19]. In this open-label study, newly diagnosed cases were randomized to prednisolone alone at a starting dose of 2 mg/kg with a predetermined tapering schedule or prednisolone plus immunosuppressants. Dosage protocols consisted of azathioprine 2.5 mg/kg for 2 months, then 50 mg/day; mycophenolate mofetil 2 g/day for 12 months; or pulsed cyclophosphamide 100 mg/month for 6 months, then bimonthly for 6 months. Primary outcomes were cumulative glucocorticoid dose, response, recurrence rate, and adverse events. Overall, there was a difference in cumulative steroid dosage (analysis of variance  $P = 0.047$ ).

#### **Azathioprine**

Adjuvant azathioprine ( $n = 30$ ) was compared with prednisolone alone ( $n = 30$ ) in Chams-Davatchi *et al.*'s multi-arm study [19]. The mean cumulative steroid dosage was significantly reduced in the azathioprine relative to the prednisolone arm (7712 mg vs 11 631 mg,  $P = 0.047$ ). The clinical response rate was similar at 24/30 versus 23/30. One patient had a treatment failure, and two patients demonstrated significant elevation of liver enzymes in the azathioprine group.

Akhtar and Hasan reported a nonrandomized controlled trial in 72 pemphigus vulgaris patients, comparing prednisolone ( $n = 40$ ), prednisolone plus azathioprine ( $n = 15$ ), and betamethasone-cyclophosphamide pulse therapy ( $n = 17$ ) [20]. The regimen consisted of prednisolone 30–120 mg/day on a tapering schedule, alone or in combination with azathioprine 100–150 mg/day. Treatment with azathioprine was more effective with regard to the proportion of patients achieving disease control (11/15 vs 13/40; response difference, 0.41; 95% confidence interval [CI], 0.14–0.68; number needed to treat, 3; 95% CI, 2–8). The frequency of relapses and the incidence of complications were lower in the azathioprine group. Eight of the 40 patients in the prednisolone arm died, compared with one of the 15 in the azathioprine arm.

Chaidemenos *et al.* reported a retrospective chart review comparing outcomes of 36 patients with oral pemphigus vulgaris treated with oral prednisolone alone, or prednisolone plus azathioprine. They noted similar overall response rates, but with lower

cumulative steroid dosages and adverse events in the azathioprine group [21].

#### **Cyclophosphamide**

Adjuvant pulsed cyclophosphamide ( $n = 30$ ) was compared with prednisone alone ( $n = 30$ ) in Chams-Davatchi *et al.*'s multi-arm study [19]. The mean cumulative steroid dosage was significantly reduced at 8276 mg versus 11 631 mg. The clinical response rate was similar at 22/30 versus 23/30. Adverse events in the cyclophosphamide group were not reported separately. Six patients in the cyclophosphamide arm were lost to follow-up and one excluded due to poor compliance.

Sethy *et al.* reported an open RCT of 28 patients with pemphigus vulgaris with active disease comparing two dosage regimens of cyclophosphamide [18]. Interventions included dexamethasone-cyclophosphamide pulse and daily oral cyclophosphamide (DCP + C) versus cyclophosphamide pulse and daily oral prednisolone (CP + P). The regimen of DCP + C consisted of pulsed dexamethasone 100 mg daily for 3 days, plus intravenous cyclophosphamide 500 mg on day 1 and oral cyclophosphamide 50 mg daily; pulses were repeated monthly for 12 months and oral prednisone 0.5–0.75 mg/kg per day was added if required. CP + P consisted of pulsed monthly cyclophosphamide 15 mg/kg per day and oral prednisolone at a starting dosage of 1.5 mg/kg per day on a predetermined tapering schedule. The primary outcome was time to remission. Results demonstrated earlier mean time to remission in the CP + P group of 8.4 weeks versus 13 weeks in the DCP + C group. Efficacy parameters and relapse rates were similar. There were increased acute steroid-related adverse events in the DCP + C group and increased long-term steroid-related adverse events in the CP + P group.

Chrysomallis *et al.* conducted an RCT of prednisone, cyclophosphamide, and cyclosporine [22]. Twenty-eight patients with newly diagnosed pemphigus vulgaris restricted to the oral cavity were randomized to prednisone equivalent 40 mg daily ( $n = 10$ ), alone or in combination with either cyclophosphamide 100 mg/day ( $n = 10$ ), or cyclosporine 5 mg/kg per day ( $n = 8$ ). All patients were followed for 5 years. There was no significant difference in the duration of treatment required to achieve disease control between cyclophosphamide and prednisone alone (mean 24 vs 28 days), relapse rate, or disease control at 5 years. Adverse events were mild, although the incidence of complications was higher with combination treatments.

A nonrandomized controlled trial comparing prednisolone, prednisolone plus azathioprine, and betamethasone-cyclophosphamide is described above [20]. Treatment was considered to have failed in 12 of the 17 patients in the pulsed cyclophosphamide arm, and the patients required additional steroids. An increased susceptibility to infection was also seen in the cyclophosphamide group and four of the 17 patients died.

In summary, cyclophosphamide appears to have a steroid-sparing benefit, although the potential adverse events are considerable. Cyclophosphamide may have a role in certain cases of refractory disease.

#### **Cyclosporine**

There have been two RCTs addressing cyclosporine in pemphigus and a number of case series. Ioannides *et al.* reported an open-label RCT of 33 patients with newly diagnosed pemphigus (29 with pemphigus vulgaris and four with pemphigus foliaceus) [23]. Treatment regimens included prednisolone 1 mg/kg ( $n = 17$ ) or

prednisolone 1 mg/kg plus cyclosporine 5 mg/kg ( $n = 16$ ), tapered and discontinued according to a standardized protocol, with follow-up of 4–6 years. There were no differences in any of the variables used to measure the response to treatment (mean 17 days in both groups), the proportion of patients able to taper steroids below 15 mg/day (12/17 and 12/16 at 12 months), the proportion of patients able to stop treatment (5/17 and 4/16 at 12 months), the time to achieve remission, or treatment failure (2/17 and 1/16). Complications were more common among patients who received combination therapy.

Similar results were reported in an RCT of cyclosporine by Chrysomallis *et al.* described above in the cyclophosphamide section [22]. There was no benefit from cyclosporine with regard to the time needed to achieve disease control, the proportion of patients responding to treatment, or the relapse rate. The incidence of adverse events, particularly hypertrichosis and renal impairment, was higher in the cyclosporine group.

From the available evidence, adjunctive cyclosporine does not appear to be beneficial in pemphigus. Efficacy does not appear to be greater than with steroids alone, and adverse events are more frequent.

### Methotrexate

No controlled trials have tested the efficacy of methotrexate in pemphigus. In a series of nine pemphigus vulgaris patients, all of whom had had been treated unsuccessfully with another adjuvant agent, Smith and Bystryn reported the use of methotrexate at dosages of 10.0–17.5 mg/week in combination with prednisone [24]. Once the disease was controlled, steroids were rapidly tapered, and six of the nine patients were able to discontinue steroids within 6 months. Adverse events were mild and included nausea and mild elevation of transaminases.

Mashkileysen and Mashkileysen reported 53 patients with pemphigus vulgaris who were treated with prednisone 60–200 mg/day and methotrexate 25–50 mg/week [25]. Treatment was reported as “effective” in 42 of the 53 patients and “ineffective” in nine, and two patients withdrew due to adverse events. There were no changes in liver enzymes, and liver biopsies performed after every 1.5 g cumulative methotrexate were unremarkable. A steroid-sparing effect was seen. The most common adverse effect was infection. Twenty-eight of 185 patients in this case series died, but the number of these who were receiving methotrexate was not reported.

There is insufficient evidence to draw conclusions regarding the role of adjuvant methotrexate in pemphigus.

### Mycophenolate mofetil

Adjuvant mycophenolate mofetil ( $n = 30$ ) was compared with prednisolone alone ( $n = 30$ ) in Chams-Davatchi *et al.*'s multi-arm study [19]. The mean cumulative steroid dosage was lower in the mycophenolate mofetil arm, at 9798 mg versus 11 631 mg, although the difference was not statistically significant. The clinical response rate was similar at 21/30 versus 23/30.

Beissert *et al.* reported a placebo-controlled RCT adjuvant mycophenolate in 96 patients with pemphigus vulgaris [26]. The interventions included mycophenolate mofetil at a dose of 2–3 g daily versus placebo. All patient also received prednisolone 1–2 mg/kg tapered according to a predetermined schedule. The primary outcome measure was response to treatment. Results demonstrated similar response rates of 40/58 (mycophenolate mofetil) versus

23/36 (placebo). The MMF group demonstrated a more rapid response to treatment (24.1 weeks vs 31.3 weeks;  $P = 0.0152$ ) and delayed time to relapse. The cumulative steroid dose was decreased at 7617.5 mg versus 8727.5 mg. There were fewer serious adverse events in the mycophenolate mofetil group, although the rate of infections was increased.

### Summary

The study by Chams-Davatchi *et al.* demonstrates a steroid-sparing benefit of adjuvant immunosuppressive agents, although no difference was observed in clinical end points. Differences in cumulative steroid dosage are a surrogate end point.

### Which immunosuppressive agent is most effective?

#### Azathioprine versus mycophenolate mofetil

Beissert *et al.* reported an RCT comparing azathioprine and mycophenolate mofetil in 40 patients with pemphigus vulgaris and pemphigus foliaceus [27]. Interventions included azathioprine 2 mg/kg versus mycophenolate mofetil 1 g b.i.d. All patients received a uniform dose of methylprednisolone. Results demonstrated similar time to response and remission rates with 13/18 in the azathioprine group and 20/21 in the mycophenolate group. There was no difference in duration of remission. Cumulative steroid dosage was similar in both groups. Adverse events were similar in both groups.

In the multi-arm trial by Chams-Davatchi *et al.* described earlier, the cumulative steroid dosage was lower in the azathioprine group than in the mycophenolate group (7712 mg vs 9798 mg;  $P = 0.007$ ) [19]. Clinical response rates were similar.

#### Azathioprine versus cyclophosphamide

Rose *et al.* conducted an open RCT comparing intravenous dexamethasone–cyclophosphamide and oral methylprednisolone–azathioprine [28]. Twenty-two patients with newly diagnosed disease (16 with pemphigus vulgaris and six with pemphigus foliaceus) were enrolled. The patients were randomly assigned to methylprednisolone 2 mg/kg plus azathioprine 2.0–2.5 mg/kg ( $n = 11$ ) or intravenous dexamethasone 100 mg/day for 3 days and cyclophosphamide 500 mg on day 1, plus oral cyclophosphamide 50 mg/day ( $n = 11$ ). The dexamethasone–cyclophosphamide pulse was administered every 2–4 weeks at increasing intervals. At 24 months, five of the 11 patients in the methylprednisolone–azathioprine group and one of the 11 in the dexamethasone–cyclophosphamide group had controlled disease on treatment; three of the 11 in each group were in remission and had stopped therapy; and one in the methylprednisolone–azathioprine group and six in the dexamethasone–cyclophosphamide group had had progression of disease. Patients who progressed on dexamethasone–cyclophosphamide were subsequently treated with the methylprednisolone–azathioprine regimen, and all improved. One patient in the methylprednisolone–azathioprine group withdrew due to generalized herpes simplex virus infection. Adverse events were reported more commonly in the methylprednisolone–azathioprine group.

In the multi-arm trial by Chams-Davatchi *et al.* described earlier, cumulative steroid dosages and clinical response rates were similar in azathioprine and cyclophosphamide groups [19].

Akhtar and Hasan reported a nonrandomized controlled trial comparing prednisolone ( $n = 40$ ), prednisolone plus azathioprine ( $n = 15$ ) and betamethasone–cyclophosphamide pulse therapy ( $n = 17$ ) in pemphigus vulgaris [20]. This trial was described in part in the section on azathioprine above. The regimen consisted

of pulsed intravenous betamethasone 100 mg/day for 3 days and cyclophosphamide 500 mg on day 1, plus cyclophosphamide 50 mg orally daily. Treatment was considered to have failed in 12 of the 17 patients in the pulsed cyclophosphamide arm, and the patients required additional steroids. An increased susceptibility to infection was seen in the betamethasone–cyclophosphamide group in comparison with other arms, and four of the 17 patients died.

### Cyclosporine versus cyclophosphamide

In the paper by Chrysomallis *et al.* described earlier, there was no significant difference in the duration of treatment required to achieve disease control between cyclosporine and cyclophosphamide (mean 25 vs 24 days), the relapse rate, or the remission rate at 5 years [22].

### Mycophenolate versus cyclophosphamide

In the multi-arm trial by Chams-Davatchi *et al.* described earlier, cumulative steroid dosages and clinical response rates were similar in the cyclophosphamide and mycophenolate groups [19].

### Does immunomodulatory therapy (i.e., plasmapheresis or intravenous immunoglobulin) improve efficacy or reduce morbidity in patients with severe or recalcitrant pemphigus?

Immunomodulatory therapies are appealing, as they target the antibodies that are directly pathogenic in pemphigus. However, because these agents/modalities are more invasive and substantially more costly, these modalities are usually reserved for patients with severe recalcitrant disease.

#### Plasmapheresis

Guillaume *et al.* randomly assigned 40 previously untreated patients with pemphigus vulgaris and foliaceus to prednisolone alone (0.5–2.0 mg/kg per day;  $n = 18$ ) or prednisolone plus 10 large-volume plasma exchanges (55 mL/kg per exchange) over 4 weeks ( $n = 22$ ) [29]. There were no differences between the two groups with respect to clinical improvement, cumulative steroid dose, or serum autoantibody titers. Eight patients (four in each group) did not achieve disease control. Four patients, all in the plasmapheresis group, died of sepsis or thromboembolism. This study suggests that plasmapheresis in association with steroids is not effective in the treatment of pemphigus. Other authors have argued that the poor efficacy of plasmapheresis in this trial is related to various aspects of the trial protocol [30,31]. Nevertheless, the high mortality rate in the plasmapheresis arm is concerning.

Eight previous case series demonstrated more promising results. The role of plasmapheresis in pemphigus is unclear. The lack of benefit and high mortality rate in this study suggest that plasmapheresis should not be recommended in patients with new-onset disease. However, the role of plasmapheresis in patients with severe recalcitrant disease is unclear.

#### Immunoadsorption

Immunoadsorption is similar to plasmapheresis, but immunoglobulins are specifically removed from the circulation. There are three case series describing immunoadsorption in pemphigus.

Lüftl *et al.* conducted a prospective case series on protein A immunoadsorption, including nine patients (seven with pemphigus vulgaris and two with pemphigus foliaceus) [32]. The treatment regimen consisted of two cycles of immunoadsorption separated by 48 h, given with a pulse of prednisolone. Patients were continued on methylprednisolone 0.5 mg/kg per day and on preexisting adju-

vant medication. All of the patients showed clinical improvement, allowing reduction of steroid doses. Antibody titers decreased by 30% after a single treatment, and IgG was preferentially eliminated in comparison with other plasma proteins. One patient had an anaphylactic reaction and immunoadsorption was discontinued.

Schmidt *et al.* described the use of immunoadsorption in five patients (four with pemphigus vulgaris and one with pemphigus foliaceus) [33]. The patients were treated with 19 cycles of immunoadsorption over 41 weeks, in addition to 0.5 mg/kg methylprednisolone, which was gradually tapered. Pulsed cyclophosphamide and dexamethasone for administered with the initial cycle of immunoadsorption. Clinical improvement was seen within 2 weeks, and the patients became lesion free in 3–21 weeks. One patient relapsed, but responded to a second induction cycle. A steroid-sparing effect was seen. Antibody titers decreased by an average of 75% at 1 month. Adverse events reported included deep vein thrombosis, bradycardia and hypertension, symptomatic hypocalcemia, and difficulty with venous access.

Shimanovich *et al.* reported a prospective case series of nine patients with pemphigus vulgaris treated with immunoadsorption, in combination with methylprednisolone 2 mg/kg and adjuvant azathioprine or mycophenolate [34]. All patients demonstrated rapid initial clinical response, with decreased circulating antibody levels. The therapy was well tolerated.

Immunoadsorption appears to be an effective treatment in inducing rapid clinical improvement, associated with decreased antibody titers and a steroid-sparing effect.

#### Intravenous immunoglobulin

There has been one RCT including 61 participants (40 pemphigus vulgaris, 21 pemphigus foliaceus) examining a single cycle of two dosage regimens of intravenous Ig against placebo [35]. Included patients had active disease, uncontrolled on prednisolone doses of 20 mg/day or more. Fourteen of the 61 patients were on concomitant immunosuppressants. The primary outcome measures was “time to escape from protocol,” defined as the time until additional therapy was required due to lack of response or disease worsening. Hazard ratios were not reported; however, there was a difference in the number of patients remaining “in protocol”: with 19/21 on 400 mg/kg over 5 days, 15/20 on 200 mg/kg, and 9/20 on placebo. The duration of response was longer in the 400 mg/kg group compared with placebo (log rank test  $P < 0.001$ ). There was an improvement in pemphigus activity score and antidesmoglein antibody titers. There was a dose–response trend, with superior results in the higher dosage group. Adverse events were similar in active and placebo arms.

### Are anti-inflammatory therapies (e.g., gold, dapsone, antibiotics) beneficial in pemphigus?

Anti-inflammatory agents are often prescribed for patients with relatively mild pemphigus, as they have a more favorable safety profile in comparison with immunosuppressants.

#### Gold

Auad and Auad described a blinded, placebo-controlled trial of adjuvant gold in 30 patients with pemphigus foliaceus [36]. The patients were initially stabilized on corticosteroids, and gold 3 mg/day or a placebo was then added. Nine of the 30 patients did not complete the trial, and an intention-to-treat analysis was not performed. The results for 10 patients treated with gold and 11 in the placebo arm were reported, with a mean follow-up of 4 years. At 12 months, a steroid-sparing effect was seen, with a mean steroid

dose of 37 mg in the placebo group and 5.5 mg/day in the gold arm. Four patients in the gold arm experienced complications, including diarrhea and proteinuria.

Four retrospective case series were indentified [37–40]. Most series have evaluated the use of gold in a population of patients with relatively mild disease. The majority of patients improved, a substantial proportion was able to stop treatment, and a small proportion failed to respond. A steroid-sparing effect was seen. Although side effects related to gold therapy were relatively mild, many patients were unable to tolerate treatment.

### Dapsone

Werth *et al.* reported an RCT that included 19 patients with pemphigus vulgaris who were unable to taper steroid below 15 mg/day after twice following a standardized prednisone-tapering schedule, plus any adjuvant, and were randomly assigned to dapsone 125–150 mg/day ( $n = 9$ ) or placebo ( $n = 10$ ), in addition to steroid and immunosuppressants [41]. Five of the nine patients receiving dapsone, in comparison with three of the 10 receiving the placebo, were able to taper steroids below 7.5 mg/day. There was a trend favoring dapsone, but statistical significance was not reached. Overall, side effects included a drug rash, paresthesias, and dyspnea secondary to methemoglobinemia.

Heaphy *et al.* reported the use of dapsone in a retrospective case series of nine patients with pemphigus vulgaris who where steroid dependent or had poorly controlled disease [42]. Dapsone was used as a third-line agent, in combination with steroids and immunosuppressive or anti-inflammatory adjuvants, at dosages of 125–150 mg/day. Seven of the nine patients were able to successfully taper steroids below 7.5 mg/day, and two patients were able to stop steroids. Two patients who had poorly controlled disease at baseline did not respond. The dapsone dose was adjusted in three of the nine patients in response to decreased hemoglobin.

Basset *et al.* reported a case series of nine previously untreated patients who received dapsone 200–300 mg/day [43]. Five patients, all with mild to moderate disease, responded with at least a 50% decrease in the extent of their disease within 15 days of starting therapy. Four patients did not respond. Three patients discontinued dapsone due to adverse events, including hemolytic anemia, toxic hepatitis, and methemoglobinemia.

### Tetracyclines

Antibiotics, including tetracycline and minocycline, have been used in pemphigus for their anti-inflammatory properties.

Calebotta *et al.* conducted a prospective case series with tetracycline [44]. Thirteen pemphigus vulgaris patients received tetracycline 2 g/day and prednisone 0.5–1.0 mg/kg per day. All patients treated with tetracycline and prednisone responded and achieved cessation of new blister formation within a mean of 5.4 days. Prednisone was able to be tapered within a mean of 17 days. Two of the 13 patients discontinued tetracycline due to adverse events, including sepsis and gastrointestinal upset.

In another case series by Alpsy *et al.*, 15 patients with pemphigus (11 with pemphigus vulgaris and four with pemphigus foliaceus) were treated with tetracycline 2 g/day and nicotinamide 1.5 g/day over 2 months [45]. Five patients were newly diagnosed and 10 had previously been treated with corticosteroids and/or immunosuppressive agents. All of the patients had active disease. At 2 months, two of the 15 patients had complete healing, four had 50% healing of lesions, and nine had no response. Three of the 15 patients had mild gastrointestinal upset. Chaffins *et al.* described 11 patients (six

with pemphigus vulgaris and five with pemphigus foliaceus) who were treated with tetracycline 2 mg/day and nicotinamide 1.5 mg/day [46]. Five of the 11 patients received concurrent prednisone (2.5–30 mg/day). At 2 months, five of the 11 patients had complete healing, four had 50% healing, and two had no response. Adverse events included gastrointestinal upset, headache, and a morbilliform eruption.

Gaspar *et al.* described 10 patients (seven with pemphigus vulgaris and three with pemphigus foliaceus) who were treated with minocycline 100 mg/day as an adjuvant [47]. Nine of the 10 patients were concurrently treated with prednisone (10–40 mg/day) and five patients also received azathioprine (100–200 mg/day). All of the patients had active disease when minocycline was commenced. Four of the 10 patients had complete clearing of lesions, two improved, and four had no response. A steroid-sparing effect was seen among responders. Minocycline was well tolerated; one patient developed pigmentation and nine developed candidiasis.

The evidence to support the use of antibiotics is inconsistent.

### Sulfasalazine and pentoxifylline

El-Darouti *et al.* reported a nonrandomized placebo controlled trial of adjuvant sulfasalazine and pentoxifylline involving 64 patients with pemphigus vulgaris [48]. Patients received concomitant pulsed steroid–cyclophosphamide therapy. Forty-two patients also received pentoxifylline 400 mg and sulfasalazine 500 mg t.d.s. A total of 86% of patients in the pentoxifylline/sulfasalazine group were classified as “excellent” clinical improvement, compared with 18% in the placebo arm. Serum tumor necrosis factor alpha titers were also decreased in the active group. Adverse events were predominantly gastrointestinal.

### Are biologicals effective and safe in pemphigus?

#### Rituximab

Rituximab has been evaluated in a number of case series. Joly *et al.* reported a prospective case series of 21 patients with corticosteroid-refractory or -dependent disease [49]. Patients were treated with a single cycle of four weekly infusions of rituximab 375 mg/m<sup>2</sup>. The number that achieved healing of all lesions by 3 months was 18/21, and the clinical response was sustained throughout the 34-month follow-up period by most patients. All patients demonstrated B-cell lymphopenia. Two patients experienced serious infections.

Horvath *et al.* reported a series of 15 patients treated with a single cycle of rituximab, involving two infusions of 500 mg 2 weeks apart [50]. Patients had varying disease severity and concomitant treatments. All patients demonstrated a clinical response, with mean time to disease control of 7 weeks, and sustained remission, with only 6/15 patients relapsing at a mean time of 97 weeks posttreatment. One patient experienced severe sepsis.

Arin *et al.* reported a case series of five patients refractory to prednisolone and azathioprine, treated with a single cycle of rituximab (375 mg/m<sup>2</sup> weekly for 4 weeks) [51]. Three out of five patients demonstrated a complete response and two out of five patients a partial response. Adjuvant immunosuppressants were able to be tapered in all patients. No serious adverse events were noted.

Lunardon *et al.* reported a retrospective series of 31 patients (24 pemphigus vulgaris, seven pemphigus foliaceus) treated with adjuvant rituximab [52]. Complete remission was achieved in 18/31 patients. Patients with shorter duration of disease before rituximab demonstrated superior response, raising the possibility that earlier treatment may decrease relapse; however, prospective studies are needed to evaluate this.

### Etanercept

Fiorrentino *et al.* reported a randomized placebo-controlled trial of etanercept for pemphigus vulgaris [53]. The trial was halted after a futility analysis after enrolment of eight patients. Treatment failed in five out of six patients in the etanercept group versus none out of two in the placebo group. Case reports have documented more positive results, possibly due to dosage considerations or heterogeneous response rates.

### Combinations therapy with rituximab and immunomodulatory therapy

Ahmed *et al.* reported a case series of 11 patients treated with refractory pemphigus vulgaris treated with rituximab and intravenous Ig [54]. The regimen involved a loading dose, then monthly infusions of both agents for 4 months. Nine of 11 patients responded, with a prolonged remission (mean 31 months). No infections were observed. The therapies were postulated to be synergistic.

Pfütze *et al.* reported a retrospective case series comparing six patients treated with immunoadsorption alone, and five patients treated with immunoadsorption and rituximab [55]. In this series, patients on combination therapy demonstrated superior clinical responses, decreased steroid dosages, and lower antibody levels.

### What is the role of adjuvant topical therapies?

Topical glucocorticoids are widely used; however, a range of novel topical therapies has been reported.

#### Clobetasol propionate

Dumas *et al.* reported a case series of seven patients with mild pemphigus vulgaris and pemphigus foliaceus who were treated with clobetasol propionate 0.05% cream alone, applied to affected sites on skin and mucosa twice daily [56]. Four of seven patients were controlled on topical therapy alone, while three patients required addition of systemic therapy.

#### Epidermal growth factor

There has been one left–right comparison RCT including 20 patients with pemphigus vulgaris with active lesions of symmetrical size and distribution [57]. All patients received concomitant systemic therapy with prednisolone with or without immunosuppressive agents. The intervention included epidermal growth factor (10 µg/g) in 0.1% silver sulfadiazine cream versus 0.1% silver sulfadiazine cream applied daily until complete healing was observed. The primary outcome measure was median healing time. Median healing time was 9 days versus 15 days (log rank  $P = 0.0003$ ). One patient developed disseminated zoster, but no other adverse effects were observed over a 9-month follow-up.

#### Nicotinamide gel

Iraji and Banan reported a left–right placebo-controlled trial of 4% nicotinamide gel involving 60 lesions of eight patients with pemphigus vulgaris [58]. Concomitant therapy included systemic corticosteroids and azathioprine. The percentage reduction in lesion surface area was greater in the nicotinamide group (26.2% vs –5.8%). One patient experienced temporary flushing.

#### Pimecrolimus

Iraji *et al.* reported a left–right placebo-controlled randomized trial of 1% pimecrolimus cream involving 62 lesions in 11 patients with pemphigus vulgaris [59]. Concomitant therapy included systemic corticosteroids and azathioprine. The percentage reduction in

lesion surface area was greater in the pimecrolimus group (15.7% vs –19.39%). Adverse effects included stinging at cream application site.

### Prostaglandin E2

Kumaran and Kanwar reported a case series of 10 patients with recalcitrant oral pemphigus vulgaris in whom systemic therapy had been discontinued [60]. The intervention included topical application of prostaglandin E2 b.i.d. to affected sites. Results were heterogeneous, with six patients improving and four patients failing therapy. Relapse upon cessation of therapy occurred within 7–10 days.

### Intralesional triamcinolone acetonide

Mignogna *et al.* reported a nonrandomized trial of adjuvant intralesional triamcinolone acetonide versus topical glucocorticoids in 35 patients with oropharyngeal pemphigus vulgaris [61]. Intralesional triamcinolone was administered at concentrations of 10 mg per lesion weekly for at least 2 weeks. The intralesional group experienced shorter time to remission (126.6 days vs 153.2 days), and lower cumulative steroid dosages (4894 mg vs 5312 mg); however, the difference was not statistically significant. Patient satisfaction and pain scores were superior in the intralesional group. Candidiasis was less common in the intralesional group (6% vs 37%).

### What therapies are available to minimize side effects of treatment?

#### Bisphosphonates

Tee *et al.* reported an RCT of 44 patients with newly diagnosed immunobullous disorders (11 pemphigus vulgaris, 11 pemphigus foliaceus) comparing oral alendronate sodium 10 mg/day versus placebo [62]. Intention-to-treat analysis was not performed. All patients received concomitant vitamin D and calcium. All patients were treated with oral prednisolone, with some patients also receiving adjuvant azathioprine or dapsone. There was a significant difference in bone mineral density (+3.5% alendronate, –1.4% placebo lumbar spine  $T$  score;  $P = 0.01$ ). No new fractures were identified in either group.

#### Key points

- Pemphigus is a rare disease, and consequently the majority of trials conducted to date have been limited by inadequate power.
- Low-dose (1 mg/kg) corticosteroids appear to be as equally effective as higher dose regimens for initial disease control.
- Pulsed corticosteroid therapy confers no additional benefit in newly diagnosed patients and is associated with increased morbidity.
- Adjunctive immunosuppressants (azathioprine, cyclophosphamide, mycophenolate mofetil) have a steroid-sparing benefit. The optimal steroid-sparing agent is not established. Cyclosporine does not appear beneficial.
- Plasmapheresis is not indicated in new-onset disease. Intravenous Ig and immunoadsorption appear to be beneficial.
- Dapsone and gold may have a steroid-sparing effect.
- Rituximab appears to prolong duration of remission, although infection rates may be increased. Etanercept does not appear to be beneficial.
- A variety of novel topical therapies may reduce healing time.
- Adjuvant bisphosphonates improve bone mineral density.
- Choice of treatment requires consideration of disease severity, co-morbidities, and evaluation of risks and benefits of therapies on an individual basis.

<sup>2</sup>Department of Dermatology, University of Pittsburgh Medical Center, Pittsburgh, PA, USA

## Background

### Definition

Sarcoidosis is a systemic, idiopathic disease characterized by the formation of noncaseating epithelioid granulomas that disrupt underlying tissue function. While sarcoidosis can affect virtually any organ system, pulmonary (>90%), hepatosplenic (50–80%), hematological (40%), musculoskeletal (39%), ocular (30–50%), cutaneous (25%), cardiac (5%), and neurological (5–10%) manifestations are most common [1,2].

Cutaneous manifestations of sarcoidosis typically present at disease onset, and – with the exception of erythema nodosum and lupus pernio – do not correlate with disease severity. Erythema nodosum tends to be associated with acute, benign, spontaneously resolving sarcoidosis, whereas the presence of lupus pernio may suggest a more treatment-refractory course [3–5]. Skin lesions in sarcoidosis can be divided into specific lesions (i.e., skin biopsy demonstrates noncaseating granulomas) and nonspecific lesions (i.e., reactive states). Specific lesions include papules, nodules, plaques, subcutaneous nodules, infiltrative scars, and lupus pernio. Multiple atypical presentations also exist (i.e., verrucous, ulcerative, and morpheaform). Plaques and papules are the most common cutaneous lesions, while lupus pernio is most specific for sarcoidosis [6]. Lupus pernio tends to affect the face, manifesting as brownish-red, dusky, swollen, and shiny infiltrated plaques [1].

### Incidence/prevalence

Sarcoidosis affects all ethnic groups, ages, and both sexes, but incidence peaks in adults under 40 years of age [7]. Sarcoidosis is most common in African-American females, whose disease is typically more acute and severe in comparison with others [8,9]. In the USA, the incidence is 10–14 per 100 000 for whites and 35.5–64 per 100 000 for African-Americans [10].

### Etiology

The etiology of sarcoidosis remains elusive, with immunologic, infectious, genetic, and environmental factors all postulated to play a role. The genetic basis for sarcoidosis has been demonstrated in

some family clusters of disease, including a fivefold increased risk of sarcoidosis in siblings and relatives of infected individuals, while spouses of sarcoidosis patients lack an increased risk [11]. Serological studies have found increased susceptibility in patients with certain class I and II human leukocyte antigen serotypes, and mutations within other immune genes, including tumor necrosis factor (TNF) gene mutations, have been seen in some populations [11–15]. Clustering of cases, and the occurrence of sarcoidosis-like granulomatous pulmonary disease in cases of beryllium exposure and first-responders in the September 11, 2001, attacks, have led investigators to search for environmental factors [12]. Occupational exposures to insecticides and pesticides carry a slightly increased risk of disease development, but some have speculated that this may be due to a microbe-rich environment [16]. While numerous pathogens have been examined, a potential causative role for mycobacteria has been the primary focus, because of the granulomatous nature of this disease, but no definitive proof (no mycobacterium cultured from sarcoidosis lesions) has emerged thus far [1]. As diagnostic techniques have become more sophisticated, evidence of either mycobacterial DNA or proteins have been found in increasing numbers of sarcoidosis samples studied [12].

### Prognosis

Sarcoidosis has a variable course, with both limited/spontaneously resolving and chronic/progressive forms of disease. Most patients with sarcoidosis do well. The disease resolves spontaneously in up to 60% of patients, and only about 5% of sarcoidosis patients will eventually die of their disease [17,18]. In the USA, patients are most likely to die of pulmonary complications such as pneumonia, pulmonary fibrosis progressing to cor pulmonale, and chronic obstructive pulmonary disease; deaths may occur due to cardiac or neurosarcoidosis as well [19].

### Diagnostic tests

Because no specific diagnostic test exists, sarcoidosis remains a diagnosis of exclusion. Diagnostic evaluation of a patient with suspected sarcoidosis may include [1,18]:

- *Detailed history and physical examination:* with emphasis on lungs, skin, eyes, nervous system, and heart.

- **Chest radiography.** The stages are not chronological:
  - Stage 1 – bilateral hilar, with or without paratracheal adenopathy;
  - Stage 2 – adenopathy with pulmonary infiltrate;
  - Stage 3 – pulmonary infiltrates only;
  - Stage 4 – pulmonary fibrosis.
- **Pulmonary function tests:** restrictive pattern with decreased diffusing capacity ( $DL_{CO}$ ).
- **Biopsy of affected tissue:** noncaseating granulomas.
- **Serum chemistries:** elevated alkaline phosphatase and/or hypercalcemia, which are not specific for sarcoidosis.
- **Angiotensin-converting enzyme levels:** generally, not a useful guide for diagnosis or monitoring of therapeutic response.
- **Electrocardiography:** cardiac sarcoidosis may be minimally symptomatic, and all patients should undergo baseline screening; additional imaging, including echocardiography, cardiac magnetic resonance, or positron emission tomography, may be necessary in select patients.
- **Expanded organ-specific testing guided by history and symptoms:** patients with neurologic symptoms may warrant further targeted imaging. Patients with a history of kidney stones may warrant detailed urine studies. Patients with abnormal calcium levels may warrant vitamin D testing. Patients with positive review of symptoms may warrant thyroid investigation. Patients with joint pains may benefit from imaging and rheumatologic consultation.

## Aims of treatment

Disfiguring skin lesions represent an indication for treatment of cutaneous sarcoidosis. Multiple available treatment modalities include topical and intralesional steroids, oral steroids, antimalarials, various immunosuppressive agents, and other medical and physical interventions. Since cutaneous sarcoidosis may spontaneously regress, and since many available therapeutic modalities carry a risk for substantial toxicity, it is important to weigh the risks and benefits carefully. Nonetheless, patients often seek treatment because of poor cosmesis produced by cutaneous sarcoidosis, especially when disease leads to disfiguring or nondisfiguring lesions on the head and neck. Additionally, in some patients, the cutaneous manifestations may improve with treatment of systemic disease, but in others the skin involvement is discordant and requires targeted skin-specific therapy. Accordingly, dermatologists should become familiarized with the evidence-based treatment options available for cutaneous sarcoidosis.

## Relevant outcomes

Outcome measures in cutaneous sarcoidosis are limited to subjective evaluation of whether therapy decreases or resolves active skin lesions. No validated scoring method is widely used for this disease, though one has recently been introduced [20]. Studies reporting response range from physician impression, to lesion counting, to comparison of before-and-after photography. The definition of disfiguring lesions is not well established among different investigators, and there is a lack of uniformity in measuring clinical end points in response to therapy due to polymorphic cutaneous manifestations.

## Methods of search

We searched the Cochrane Library for “sarcoidosis or sarcoid.” We searched MedlinePubMed from 1966 to 2012 using the terms “cutaneous sarcoidosis,” or “sarcoidosis,” or “lupus pernio” and “therapeutics,” or “treatment,” or “prednisone,” or “steroids,” or

“glucocorticoids,” or “allopurinol,” or “chloroquine,” or “hydroxychloroquine,” or “antimalarial,” or “methotrexate,” or “thalidomide,” or “leflunomide,” or “mycophenolate mofetil,” or “azathioprine,” or “pentoxifylline,” or “apremilast,” or “tretinoin,” or “isotretinoin,” or “tetracyclines,” or “minocycline” or “allopurinol,” or “tacrolimus,” or “infliximab,” or “adalimumab,” or “etanercept,” or “alefacept,” or “tranilast,” or “chlorambucil,” or “colchicine,” or “cyclosporine,” or “ultraviolet,” or “photodynamic therapy,” or “surgery,” or “intralesional,” or “pulse dye laser,” or “laser” as subject headings or titles or key words.

## Questions

### Case scenario 66.1

The patient is a 44-year-old African-American woman with a 14-year history of sarcoidosis. The patient has asymptomatic pulmonary involvement that does not require treatment. However, she is requesting treatment for noticeable facial lesions (Figure 66.1).

### What are the effects of systemic therapeutic interventions in patients with cutaneous sarcoidosis?

#### Oral steroids

##### Benefits

Oral glucocorticoids are used in systemic sarcoidosis because of their anti-inflammatory and immunosuppressive actions, and are often offered as first-line treatment for cutaneous sarcoidosis [21,22] despite scant, and largely anecdotal, evidence to support their use for this indication [23–33].

Mosam and Morar treated 30 patients with cutaneous sarcoidosis, of which, none of 30 responded to systemic steroids alone. These patients required a sequential therapeutic ladder (chloroquine, methotrexate, doxycycline, allopurinol, isotretinoin, azathioprine, thalidomide) to help achieve a positive clinical outcome [34]. Ramos-Casals *et al.* reviewed the literature on patients with cutaneous sarcoidosis triggered by antiviral therapy for hepatitis C virus infection. They noted nine patients treated with glucocorticoids had improvement in skin lesions and 11 with skin involvement had improvement with the discontinuation with antiviral therapy alone [35]. Jung and Roh noted therapy with oral glucocorticoids alone allowed partial responses in seven of eight patients with specific lesions of cutaneous sarcoidosis [36].

Figure 66.1 Cutaneous sarcoidosis.

### Harms

The multiple complications of steroid therapy are well known, and their likelihood and severity correlate with the length of administration. Complications may include glucose intolerance, increased susceptibility to infection, osteoporosis, avascular bone necrosis, cataracts, and neuropsychiatric changes [37]. A study of 441 sarcoidosis patients with a mean of two organ systems involved treated with prednisone who were followed for a mean of 2.9 years revealed that greater use of systemic corticosteroids was associated with a small but significant rise in health-care utilization related to infections and emergencies not directly attributable to sarcoidosis [38].

### Comments/implications for clinical practice

There are no randomized controlled trials (RCTs) or systematic reviews to support the use of oral steroids for cutaneous sarcoidosis. In the articles reviewed above, 17 of 56 patients treated with oral steroids as monotherapy had positive results. This is insufficient evidence to conclude that oral steroids are effective in cutaneous sarcoidosis. Hence, large RCTs are needed to establish clear benefit. Despite the lack of definitive studies showing the effectiveness of oral steroids in cutaneous sarcoidosis, many dermatologists still use them as first-line therapy, since steroids reverse the manifestations of pulmonary and other extrapulmonary manifestations of disease [7,37].

### Antimalarials

Antimalarials, such as chloroquine and hydroxychloroquine, are 4-aminoquinolones, and represent an effective therapy for connective-tissue diseases. Their immunomodulatory properties form the rationale for their use in cutaneous sarcoidosis.

### Benefits

While there are no RCTs to support the effectiveness of antimalarials in cutaneous sarcoidosis, their benefit has been reported in a number of open, nonrandomized, noncontrolled, prospective studies. In a 1991 comprehensive literature review of antimalarials in cutaneous sarcoidosis, Zic *et al.* concluded that chloroquine should be strongly considered in patients for whom the main indication for treatment is disfiguring cutaneous lesions, while corticosteroids should remain first-line treatment for patients with extracutaneous sarcoidosis [39]. The authors recommended an initial 14-day course of chloroquine, 500 mg/day, followed by long-term therapy with 250 mg/day, on the basis of published data [40–45]. In addition, Ben Jennet *et al.* noted in a review of 28 cases of cutaneous sarcoidosis that seven of 13 patients treated with chloroquine ameliorated their disease [46]. Modi and Rosen reported three cases of micropapular cutaneous sarcoidosis responsive to hydroxychloroquine at 200 mg twice daily [47].

Meyersburg *et al.* in 2011 reported a single case of ulcerative cutaneous sarcoidosis of the leg responding to hydroxychloroquine and compression therapy [48].

### Harms

Long-term administration of either chloroquine or hydroxychloroquine may lead to various ocular complications, the most serious of which are irreversible retinopathy and blindness [39]. Hydroxychloroquine has a lower risk of ocular toxicity, but also less effectiveness in sarcoidosis [18,39]. Thus, periodic ophthalmological examinations should be carried out in any patient on long-term therapy [49,50]. Other common side effects include nausea and vomiting, gastrointestinal upset, central nervous system toxicity

(irritability, nervousness, depression), neuromuscular reactions (skeletal muscle palsies, myopathy, or neuromyopathy), and cutaneous pigmentation. Millard *et al.* reported drug-induced bullous pemphigoid in a male patient treated with 3 months of chloroquine for sarcoidosis [51].

### Comments/implications for clinical practice

The articles summarized above describe experience with a total of 120 patients treated with antimalarials, 93 of whom had a positive result. While none of these articles represents a large RCT, these studies as a whole suggest that chloroquine and hydroxychloroquine represent a reasonable treatment option for patients with cutaneous sarcoidosis.

### Methotrexate

Methotrexate is a dihydrofolate reductase inhibitor widely used in the treatment of neoplastic diseases owing to its antiproliferative actions, and in chronic inflammatory conditions as a nonsteroidal immunosuppressant.

### Benefits

There are no RCTs or systematic reviews of methotrexate in cutaneous sarcoidosis [52,53], and the evidence for its effectiveness is based on open, nonrandomized, noncontrolled studies. In the first study of methotrexate for cutaneous sarcoidosis, Veien and Brodthagen reported clearance of skin lesions in 12 of 16 patients treated with 25 mg/week. Two patients discontinued treatment because of nausea [53]. Lower and Baughman reported improvement of cutaneous disease in 16 of 17 patients treated with methotrexate as a steroid-sparing agent for over 2 years (the average dose in the 55 study patients was 28 mg/day) [54]. Kaye *et al.* reported complete regression of severe recalcitrant cutaneous sarcoidosis in one patient, and significant improvement in three patients, treated with methotrexate, 10 mg/week, for 30 months [55]. Gedalia *et al.* reported resolution of cutaneous sarcoidosis in two of three pediatric patients treated with 10–15 mg/week of methotrexate, with significant reduction of oral steroid doses while on methotrexate [56]. Lacher reported improvement of steroid-resistant cutaneous sarcoidosis in one patient after the initial combination of prednisone 75 mg three times weekly and methotrexate 40 mg twice weekly, followed by methotrexate 7.5 mg twice weekly and eventual tapering of the steroid [57]. Webster *et al.* reported improvement of severe steroid-resistant cutaneous sarcoidosis in three patients after methotrexate 15.0–22.5 mg/week [58]. Henderson *et al.* reported improvement of cutaneous sarcoidosis in a male patient with steroid-resistant laryngeal and cutaneous disease after 10 mg/week of methotrexate [59]. Gary *et al.* reported complete remission of recalcitrant cutaneous sarcoidosis in three of four patients after treatment with methotrexate at dosages ranging from 12.5 mg/week to 30 mg/week after a mean treatment duration of 29 months. Side effects of methotrexate were observed in one patient (elevated liver enzymes), leading to discontinuation of methotrexate [60].

### Harms

Complications of methotrexate therapy include bone-marrow suppression, nausea and vomiting, hepatotoxicity, and hypersensitivity pneumonitis [37]. Albertini *et al.* described a patient with severe systemic and ulcerative sarcoidosis who was started on methotrexate 25 mg/week [61]. Although her ulcerative lesions initially regressed, she soon developed anemia, leukopenia, and an elevated aspartate transaminase level, necessitating the withdrawal of

methotrexate. The patient subsequently died of her disease. Major toxic effects noted by Lower and Baughman were hepatotoxicity, leukopenia, and cough [54]. However, a patient with cutaneous and bone-marrow sarcoidosis had improvement of anemia and leukopenia with combination methotrexate and mycophenolate mofetil [62].

#### **Comments/implications for clinical practice**

The articles published to date describe experience with a total of 50 patients with cutaneous sarcoidosis treated with methotrexate, of whom 42 had positive results. While none of these articles represents a large RCT, and there is little consistency across the trials with regard to the patient population, dosage, or clinical end points, the aggregate evidence from these studies suggests that methotrexate might be useful as a steroid-sparing agent in patients who require an additional or alternative therapeutic option.

#### **Mycophenolate mofetil**

Mycophenolate mofetil acts via inhibition of purine synthesis, blocking proliferation of T- and B- lymphocytes. It is approved for renal allograft rejection prevention and heart transplant immunosuppression, and used in a variety of inflammatory disorders.

#### **Benefits**

Kouba *et al.* reported one series of five patients with sarcoidosis involving the skin, all of whom showed improvement on doses ranging from 30 to 45 mg/kg per day, with improvement noted on average at 3 months of therapy [63]. Notably, these patients were also receiving hydroxychloroquine and systemic corticosteroids, but were able to dose-reduce their systemic steroids while on mycophenolate therapy.

#### **Harms**

Generally, mycophenolate is well tolerated, with some patients noting gastrointestinal discomfort that may be dose dependent; the study above noted no adverse effects. As an immunosuppressive medication, mycophenolate mofetil can increase the incidence of infections, including zoster.

#### **Comments/implications for clinical practice**

There is a lack of high-quality data; the one study published regarding mycophenolate for cutaneous sarcoidosis noted improvement and successful systemic corticosteroid dose reduction with no adverse events in a small series of patients. This is insufficient evidence to conclude that mycophenolate is beneficial for the treatment of cutaneous sarcoidosis. RCTs will therefore be necessary to evaluate fully the efficacy and long-term safety in patients with cutaneous sarcoidosis.

#### **Leflunomide**

Leflunomide is an anti-inflammatory cytotoxic drug that inhibits pyrimidine synthesis. It is used in the management of patients with rheumatoid arthritis. The drug exerts its effects via a reversible selectivity for proliferating lymphocytes [64]. Anti-inflammatory properties form the basis of its use in cutaneous sarcoidosis.

#### **Benefits**

Majithia *et al.* reported 20 mg/day of leflunomide allowing marked improvement in the skin rash of sarcoidosis in a patient that failed methotrexate, hydroxychloroquine, and prednisone [65]. Baughman and Lower in 2004 studied the use of leflunomide in 32 patients

with sarcoidosis who had multiorgan involvement, including skin, and noted 12 of 17 who completed treatment had a complete or partial response, though cutaneous response was not specifically commented on [66].

#### **Harms**

The advantage of leflunomide has been its toxicity profile is less than that of other immunosuppressants. However, patients may experience gastrointestinal side effects and infrequently cutaneous significant drug reactions [64–66].

#### **Comments/implications for clinical practice**

The articles published to date describe only one case of cutaneous disease responding, though Baughman and Lower's results are not specifically commented on. Patients had only mild or moderate side effects. This is insufficient evidence to conclude that leflunomide is beneficial for the treatment of cutaneous sarcoidosis, particularly because cutaneous sarcoidosis often resolves spontaneously. RCTs will therefore be necessary to evaluate fully the efficacy and long-term safety of leflunomide in patients with cutaneous sarcoidosis.

#### **Thalidomide**

Thalidomide was originally marketed as a sedative, but was withdrawn in 1962 because of its teratogenic effects [67]. Thalidomide at low doses is effective in the treatment of erythema nodosum leprosum and lupus erythematosus [68]. Thalidomide inhibits TNF- $\alpha$ , interferon gamma and interleukin (IL)-12, and increases IL-2. TNF- $\alpha$  and interferon gamma are the major cytokines that drive granulomatous inflammation in sarcoidosis, while IL-2 counteracts the effects of interferon gamma and TNF- $\alpha$  [69]. Based on its mechanism of action, thalidomide may be effective in the treatment of cutaneous sarcoidosis.

#### **Benefits**

There are no RCTs or systematic reviews of thalidomide in cutaneous sarcoidosis. Estines *et al.* reported complete regression of severe and disfiguring recalcitrant cutaneous sarcoidosis in three patients and incomplete regression in four among 10 patients treated with thalidomide 1.84 mg/kg. The dose was gradually reduced for five of the seven responders; three of the five relapsed, but improved after restarting at the same dose [70]. Baughman *et al.* reported an open-label, dose-escalation trial of thalidomide in 14 patients with lupus pernio unresponsive to prior therapy who completed 4 months of thalidomide. All patients experienced some subjective improvement of skin lesions, and 10 of 12 evaluable patients showed objective improvement using photograph scoring. Five patients improved after 1 month (treated with 50 mg/day of thalidomide), seven more patients improved after 2 months (treated with 100 mg/day of thalidomide in the second month), and two patients required an additional month of 200 mg/day of thalidomide to achieve a response [71].

A retrospective evaluation of thalidomide 100–200 mg/day in 12 patients with cutaneous sarcoidosis, by Nguyen *et al.*, found that lesions regressed in 10 of 12 treated patients within 1–5 months of therapy, with an average time of 2–3 months. Four of the patients achieved complete responses, six had partial responses, and two showed no response [72]. In an open study by Oliver *et al.*, five of eight patients with chronic cutaneous sarcoidosis had flattening of skin lesions, while one developed enlarging and ulcerating skin lesions, after 16 weeks of thalidomide. Treatment was started at an initial dosage of 50 mg/day, and doubled monthly to a maximum

dosage of 200 mg/day. All lesions became hyperpigmented during the study period, which the authors characterized as an improvement, and all follow-up biopsies showed decreased granuloma size and decreased epidermal thickness. After discontinuing thalidomide, all of the treated patients relapsed [73].

Carlesimo *et al.* reported clinical improvement of steroid-resistant cutaneous sarcoidosis in a 56-year-old woman after 2 weeks of thalidomide 200 mg/day, followed by 100 mg/day for 11 weeks [67]. Rousseau *et al.* reported clinical improvement of recalcitrant cutaneous sarcoidosis in a 30-year-old woman after thalidomide 100 mg/day for 2 months, gradually tapered to a maintenance dose of 50 mg/day [68]. Lee and Koblenzer reported clinical improvement of cutaneous sarcoidosis in a 59-year-old patient after thalidomide 200 mg/day for 2 months and 300 mg/day for 4 months [74]. Hoch *et al.* reported almost complete resolution of generalized or disseminated cutaneous sarcoidosis in two patients after 8–12 months of treatment with thalidomide, initially with 200 mg/day and later with 100 mg/day [75]. Walter *et al.* reported rapid improvement of therapy-resistant long-standing cutaneous sarcoidosis in a 36-year-old man after thalidomide 50 mg/day, without major adverse effects [76]. Fazzi *et al.* treated 19 sarcoidosis patient with cutaneous and pulmonary disease for 24 months (200 mg/day for 2 weeks, then 100 mg/day for 11 weeks, followed by 100 mg every other day for 35 weeks, then tapered). Significantly ( $P < 0.05$ ) lower skin scores occurred at 3- (6/19) and 6-month (12/18) evaluations. However, 42% of the patients discontinued therapy due to developing symptoms of neuropathy [77]. Notably, Doherty and Hsu noted no response to thalidomide in two patients with cutaneous sarcoidosis [78].

### Harms

Thalidomide therapy may be complicated by neurosensory, gastrointestinal, and teratogenic effects [67,74]. In their analysis of thalidomide for cutaneous sarcoidosis, Baughman and Lower reported that the most serious adverse effect is peripheral neuropathy, which often resolves by reducing the dose or discontinuing the medication [79]. Baughman *et al.* noted neuropathy in seven of 14 patients, somnolence in nine patients, dizziness in two patients, constipation in six patients, rash in one patient, and increasing shortness of breath in one patient [71]. Nguyen *et al.* also noted nasopharyngeal, pulmonary, hepatic, and neurologic side effects in their retrospective analysis, and reported one patient who developed deep vein thrombosis while on thalidomide [72].

### Comments/implications for clinical practice

The articles published to date describe experience with 69 patients treated with thalidomide, 50 of whom had positive results. While none of these articles represents a large RCT, and there is inconsistency across the trials with regard to patient population, dosage, and clinical end points, the aggregate evidence from these studies suggests that thalidomide may represent a reasonable alternative or additional therapeutic option in cutaneous sarcoidosis. A large RCT will thus be necessary in order to obtain definitive proof.

### Tetracyclines

Tetracyclines are antibiotics that inhibit T-cell proliferation and granuloma formation in vitro [80], which forms the rationale for their use in cutaneous sarcoidosis.

### Benefits

There are no RCTs or systematic reviews of tetracyclines in cutaneous sarcoidosis. In one nonrandomized, noncontrolled, open pro-

spective study, eight of 12 patients with recalcitrant cutaneous sarcoidosis had complete regression, two had partial regression, and two had treatment failure (one progressed and one remained stable) after 12 months of minocycline 200 mg/day. After withdrawal of therapy, three of the 10 responders relapsed [80]. Antonovich and Callen reported complete clearance of lesions in a patient with cutaneous sarcoidosis induced by cosmetic tattoo after a 4-month course of doxycycline 100 mg twice a day combined with a mid-potency topical steroid [81]. Additional case reports reported similar resolution of cutaneous sarcoidosis both with minocycline and doxycycline therapy [82,83].

### Harms

General side effects of tetracyclines include photosensitivity, gastrointestinal symptoms, and pseudotumor cerebri. Side effects of minocycline include nausea and vomiting, hypersensitivity reactions, blue skin pigmentation, and vertigo [80]. Hypersensitivity was noted in one patient in this study [80].

### Comments/implications for clinical practice

The articles published to date describe experience with a total of 15 patients treated with tetracyclines, 13 of whom had positive results. While this is insufficient evidence to conclude that tetracyclines are beneficial for the treatment of cutaneous sarcoidosis and a large RCT will be necessary for definitive proof, tetracyclines may represent an easy alternative to oral steroids or other medications with a more serious side-effect profile.

### Allopurinol

Allopurinol is a xanthine oxidase inhibitor used in the treatment of gout and other inflammatory diseases. Its anti-inflammatory properties form the basis for its use in cutaneous sarcoidosis.

### Benefits

There are no RCTs or systematic reviews of allopurinol in cutaneous sarcoidosis. In one nonrandomized, uncontrolled, open prospective study, four of six patients with cutaneous sarcoidosis had improvement of skin lesions after treatment with allopurinol, starting at 100 mg/day and increased to 600 mg/day by 100 mg every 2–4 weeks [84]. Bregnhøj and Jemec reported a positive response in four of seven patients with cutaneous sarcoidosis who were treated with low-dose allopurinol [85]. Pfau *et al.* reported complete resolution of scar sarcoidosis in two patients and partial resolution of nodular sarcoidosis in two patients after treatment with allopurinol 300 mg/day over a 3–7-month period [86]. Rosof reported remission of cutaneous sarcoidosis in two patients treated with allopurinol [87]. Pollock reported marked improvement of cutaneous sarcoidosis lesions in two patients after treatment with allopurinol, either 100 mg/day or 300 mg/day [88]. Brechtel *et al.* reported improvement of recalcitrant disseminated cutaneous sarcoidosis in one patient after allopurinol 300 mg/day [89]. Antony and Layton reported improvement of recalcitrant cutaneous acral sarcoidosis after allopurinol 300 mg/day [90]. El-Euch *et al.* reported improvement in one child after allopurinol 200 mg/day [91]. Notably, Voelter-Mahlknecht *et al.* reported one patient whose cutaneous sarcoidosis progressed while on allopurinol [92].

### Harms

Allopurinol therapy may be complicated by a drug rash (including a severe reaction, such as toxic epidermal necrolysis), as well as nausea and vomiting, hepatotoxicity, and bone-marrow suppression [89].

### Comments/implications for clinical practice

The articles published to date describe experience with a total of 26 patients treated with allopurinol, 20 of whom had a positive result. This is insufficient evidence to conclude that allopurinol is beneficial for treatment of cutaneous sarcoidosis, particularly because cutaneous sarcoidosis often resolves spontaneously. Large RCTs will be necessary for definitive proof.

### Isotretinoin

Isotretinoin, a retinoid that inhibits sebaceous gland function and keratinization, is useful in the treatment of many dermatological conditions. The immunomodulatory effects of isotretinoin form the basis for its use in cutaneous sarcoidosis [93].

### Benefits

There are no RCTs or systematic reviews of isotretinoin in cutaneous sarcoidosis. Georgiou *et al.* described complete resolution of recalcitrant, long-standing cutaneous sarcoidosis in a 31-year-old woman after 8 months of isotretinoin 1 mg/kg per day [93]. Waldinger *et al.* reported resolution or improvement of many long-standing severe disfiguring and recalcitrant lesions in a woman after 30 weeks of isotretinoin (initially 40 mg/day for 6 weeks, increased to 80 mg/day for 16 weeks, and decreased back to 40 mg/day for the last 8 weeks because of side effects) [94]. Spiteri and Taylor reported negligible resolution of chronic cutaneous sarcoid nodules in a woman treated with isotretinoin, 75 mg/day (decreased to 50 mg/day because of cheilitis), whose exfoliative dermatitis prompted drug withdrawal after 7 weeks [95]. Vaillant *et al.* reported improvement of recalcitrant cutaneous sarcoidosis in a woman after 6 months of isotretinoin 0.4–1.0 mg/kg per day [96]. Mosam and Morar reported clearance of multitherapy-resistant cutaneous sarcoidosis in one patient after 6 months of isotretinoin therapy at 25 mg/day [34]. Chong *et al.* reported on a series of patients, one of whom was a Chinese patient with acne and sarcoidosis who obtained a partial response to isotretinoin [97].

### Harms

Isotretinoin is a teratogenic drug and must not be used by women who are pregnant or who become pregnant during treatment. Other side effects include visual impairment, hepatic dysfunction, and pancreatitis. Side effects noted by study participants included myalgia, xerosis, dryness of nasal mucosa, cheilitis, and exfoliative dermatitis [93,94,96].

### Comments/implications for clinical practice

The articles published to date describe experience with six patients treated with isotretinoin, five of whom had a positive result. This is insufficient evidence to conclude that isotretinoin is beneficial for the treatment of cutaneous sarcoidosis, particularly because cutaneous sarcoidosis often resolves spontaneously. Large RCTs will be necessary for definitive proof.

### Fumaric acid esters

Fumaric acid esters (FAEs) represent a form of immunomodulatory therapy that has been used successfully in Europe for the treatment of psoriasis. FAEs inhibit the pathogenetic mechanisms of granuloma formation, namely the downstream effects of TNF- $\alpha$ , maintenance of a Th1 environment, and proliferation of lymphocytes [98,99]. FAEs may therefore have efficacy in treatment of cutaneous sarcoidosis.

### Benefits

There are no RCTs or systematic reviews of FAEs in cutaneous sarcoidosis. Breuer *et al.* treated 11 patients with recalcitrant cutaneous sarcoidosis with FAE. Three of the patients treated with five or six tablets per day for 12–23 months had significant improvement of disease, while three of the patients treated with four to six tablets for 4–7 months had slight to moderate improvement of disease. Treatment was discontinued in five of the patients due to a lack of effect, and four of the patients had side effects that prompted discontinuation of therapy, including leukopenia, nausea, proteinuria, and flushing [99]. Gutzmer *et al.* reported a 61-year-old woman with cutaneous sarcoidosis whose lesions markedly improved after 12 months of therapy with FAEs. A recurrence of cutaneous disease 18 months after discontinuation was treated successfully with a 2-month course of FAEs [100]. Nowack *et al.* reported on three women with recalcitrant cutaneous sarcoidosis whose disease completely cleared after 4–12-month courses of FAEs dosed in accordance with the standard therapy regimen for psoriasis. Side effects included flushing, minor gastrointestinal complaints, and lymphopenia [101]. In addition, Dummmler *et al.* described two patients with cutaneous sarcoidosis, one of whom who had a significant improvement after 4 months of treatment with FAE; the second patient showed a slight therapeutic response after 2 months of therapy [102]. Wolter *et al.* reported an individual with resolution of cutaneous and pulmonary sarcoidosis over an 11-month course of FAE therapy [103], while Klein *et al.* reported a partial clearance in the skin lesions of one sarcoidosis patient treated with fumarate therapy [104].

### Harms

FAEs have been associated with several types of side effects in most treated patients with granulomatous skin diseases. The most frequent side effects of FAEs are flushing and diarrhea. Others include abdominal discomfort, nausea, flatulence, lack of appetite, and fatigue [34]. FAEs may produce leukopenia, relative lymphopenia, eosinophilia, and elevation of liver function tests, all of which resolve spontaneously after dose reduction or discontinuation of the treatment [98]. Hoefnagel *et al.* have evaluated the long-term safety of FAEs in 66 patients with severe psoriasis, 41 of whom received FAEs for at least 1 year and 12 of whom had received FAEs for 10–14 years. Seventy-three percent of the patients reported adverse events, which were usually mild and mainly consisted of flushing (55%), diarrhea (42%), nausea (14%), fatigue (14%), and abdominal complaints (12%). Seventy-six percent of the patients had relative lymphocytopenia during therapy with FAEs, and 14% and 25% of the patients had transient eosinophilia and moderate liver enzyme elevations, respectively. The authors concluded that FAEs are a safe long-term treatment in patients with severe psoriasis [105].

### Comments/implications for clinical practice

The articles published to date describe positive results in 14 of 19 patients in whom FAE therapy led to improvement or resolution of disease. Patients had only mild or moderate side effects. This is insufficient evidence to conclude that FAEs are beneficial for the treatment of cutaneous sarcoidosis, particularly because cutaneous sarcoidosis often resolves spontaneously. RCTs will therefore be necessary to evaluate fully the efficacy and long-term safety of FAEs in patients with cutaneous sarcoidosis.

### Phosphodiesterase inhibitors

Pentoxifylline is a nonspecific inhibitor with anti-inflammatory properties demonstrated by its ability to inhibit IL-2, IL-2 receptor

expression, and TNF production. Park *et al.* reported its steroid-sparing effects in the treatment of pulmonary sarcoidosis in an RCT [106]. However, no skin disease was evaluated in this article, and review of the literature reveals no data of its use for cutaneous sarcoidosis. A new-generation phosphodiesterase type 4 inhibitor, Apremilast, which has similar anti-inflammatory properties, has been used in treatment of cutaneous sarcoidosis [107].

### Benefits

Owing to apremilast's tendency to cause less gastrointestinal disturbance compared with pentoxifylline, it has been used in an open noncontrolled trial of 15 patients with chronic cutaneous sarcoidosis that had been unresponsive to systemic therapy for 3 months prior to entry to the study [107]. Apremilast was given at 20 mg twice a day. A total of 46 skin lesions were evaluated for induration, erythema, desquamation, and area of involvement. A significant reduction in induration score only was noted ( $P < 0.05$ ) at 12 weeks. Currently, apremilast is not available in the USA.

### Harms

Apremilast appeared well tolerated in the Baughman *et al.* study [107]. Only two of 15 patients required a dose reduction to 20 mg once daily because of jitteriness and nausea.

### Comments/implications for clinical practice

The articles published to date describe positive results in 15 patients that had a total of 46 indurated skin lesions of sarcoidosis. Patients had only mild or moderate side effects. This is insufficient evidence to conclude that apremilast is beneficial for the treatment of cutaneous sarcoidosis, particularly because cutaneous sarcoidosis often resolves spontaneously. RTCs will therefore be necessary to evaluate fully the efficacy and long-term safety of FAEs in patients with cutaneous sarcoidosis.

### Biologic anti-TNF- $\alpha$ agents

Monoclonal anti-TNF- $\alpha$  antibodies (infliximab, adalimumab) as well as the soluble anti-TNF- $\alpha$  receptor (etanercept) neutralize soluble and cell-bound TNF- $\alpha$ , and have been widely used in the treatment of psoriasis and inflammatory bowel disease in the past 15 years. The antibodies appear to have increased potency in comparison with the soluble receptor due to their cytolytic effects against immune cells with membrane-resident TNF- $\alpha$ . The use of these agents – infliximab, in particular – has been associated with suppression of TNF- $\alpha$ -mediated granulomatous responses, leading to exacerbation of pulmonary tuberculosis, possible exacerbation of demyelinating central nervous system disease, and immunosuppression, leading to increased risk of serious infection and possibly decreased immunosurveillance against malignancy [108]. Since TNF- $\alpha$  appears to be a key mediator of granuloma development in sarcoidosis [108,109], these biologic treatments have been employed to treat isolated cases of cutaneous sarcoidosis. There are no RCTs or systematic reviews of the role of biologic anti-TNF- $\alpha$  agents in the treatment of cutaneous sarcoidosis. Evidence regarding their efficacy has been presented in case series and case reports.

### Benefits

**Infliximab** Doty *et al.* reported significant improvement of cutaneous sarcoidosis in five patients and resolution in one patient among six patients with recalcitrant cutaneous disease after treatment with infliximab for cutaneous and/or visceral disease using conventional dosing regimens. Some of the patients received concomitant pred-

nisonone therapy. Infliximab was generally well tolerated in all patients. Noted adverse events included a drug reaction in one patient after several months of therapy, oral candidiasis in one patient, and angioimmunoblastic lymphoma in one patient [110]. Heffernan and Anadkat reported 90% clearance of severe recalcitrant cutaneous sarcoidosis in a 51-year-old African-American woman treated at weeks 0, 2, and 6 with 5 mg/kg of infliximab. She experienced no adverse events during therapy [111]. Haley *et al.* reported flattening of all cutaneous sarcoidosis lesions in a 39-year-old African-American man with severe and recalcitrant cutaneous sarcoidosis, after treatment at weeks 0, 2, and 6 with 5 mg/kg of infliximab and concomitant oral prednisone. Notably, prednisone alone was ineffective, and the prednisone dose was tapered significantly over the course of therapy with infliximab. The patient did not experience any adverse effects associated with infliximab therapy [108].

Baughman and Lower reported improvement in two patients with persistent recalcitrant lupus pernio after treatment with infliximab 5 mg/kg at weeks 2, 4, and 12, without any significant adverse events [112]. Mallbris *et al.* reported substantial clinical improvement of severe recalcitrant cutaneous sarcoidosis in a 39-year-old white man after 5 mg/kg treatment with infliximab at weeks 0, 2, 4, 6, and 14 when combined with concomitant methotrexate administration to prevent anti-infliximab antibody production. Notably, methotrexate alone did not produce any clinical effect. The clinical effect of infliximab therapy was noticeable after the first treatment, and became significant after the fourth treatment. The patient experienced no adverse effects [109]. Meyerle and Shorr reported complete resolution of cutaneous sarcoidosis in a female patient after initiation of infliximab [113]. Pritchard and Nadarajah reported rapid resolution of cutaneous sarcoidosis in a 32-year-old white woman with multiorgan involvement. Skin nodules disappeared after 2 days of infliximab therapy. The authors reported no adverse effects, with the exception of infusion-associated complications [114]. Roberts *et al.* reported a single case of multisystem sarcoidosis with oculocutaneous improvement after infliximab [115]. Rosen and Doherty reported a single case with dramatic response with 3.5-year follow-up [116]. Sweiss *et al.* reported eight patients, two of whom had skin involvement, treated with infliximab, with the cutaneous disease improving in one and resolving in the other; treatment was well tolerated in all cases [117]. Saleh *et al.* used infliximab in 12 patients with multisystem disease, five of whom had skin disease; four of the five experienced improvement with infliximab [118]. Of the 12 patients, one died of a ruptured blood vessel and was found to have a plasma cell dyscrasia.

Baughman *et al.* conducted a large randomized study comparing placebo with infliximab at 3 or 5 mg/kg in 138 patients; skin disease was not specifically evaluated, but 19 of the patients had lupus pernio at baseline, with four of the patients who received 5 mg/kg responding, and none of the patients who received 3 mg/kg responding [119]. Therapy was generally well tolerated throughout the study. In one large retrospective study, Stagaki *et al.* evaluated the treatment regimens of 54 patients with lupus pernio and noted that those treated with infliximab had a better response than other regimens used, with nine of 13 responding to therapy [120]. Sené *et al.* described nine patients with refractory cutaneous sarcoidosis treated with infliximab at 5 mg/kg, with varying infusion regimens, and noted excellent responses, with three patients demonstrating resolution, three demonstrating good response, and two others improving [121].

**Adalimumab** Philips *et al.* reported resolution of a severe ulcerative recalcitrant cutaneous sarcoidosis nodule in a 55-year-old white woman after a 9-week course of adalimumab 40 mg per week. The patient was concomitantly on prednisone, and the dosage was reduced progressively after initiation of adalimumab therapy. The patient experienced no adverse events [122]. Heffernan and Smith reported significant improvement of severe and ulcerating recalcitrant cutaneous sarcoidosis in an African-American woman after 10 weeks of treatment with adalimumab 40 mg weekly, with clinical effects readily apparent after five treatments. She was concomitantly being treated with hydroxychloroquine and pentoxifylline, which by themselves had no clinical effect. The patient experienced no adverse effects [123]. Judson reported one case of recalcitrant lupus pernio responding to adalimumab 40 mg subcutaneous injections weekly after 9 months of therapy [124].

**Etanercept** Khanna *et al.* reported significant improvement of cutaneous sarcoidosis in a 50-year-old African-American woman 2 months after the addition of etanercept 25 mg twice weekly to her regimen of prednisone, hydroxychloroquine, and methotrexate. Etanercept was discontinued transiently during treatment of cellulitis [125]. Tuchinda and Wong reported a single patient who partially responded to etanercept 50 mg twice weekly who had previously failed to respond to prednisone, hydroxychloroquine, and methotrexate [126].

### Harms

Complications of anti-TNF- $\alpha$  biologic agents include infusion reactions (with intravenously administered infliximab), injection reactions (with subcutaneously administered adalimumab and etanercept), exacerbation of preexisting tuberculosis, exacerbation of demyelinating neurologic disease, and immunosuppression that may lead to an increased risk of infection and decreased cancer immunosurveillance. Evaluation with a purified protein derivation test (and chest radiography if the test is positive) is therefore necessary before treatment is started, and a thorough history and physical are mandatory to elicit a prior or family history of demyelinating disorders, malignancies, and risk for malignancy [127].

### Comments/implications for clinical practice

The articles published to date describe numerous small retrospective studies demonstrating improvement in cutaneous sarcoidosis, including lupus pernio, treated with infliximab, two treated successfully with adalimumab, and one treated successfully with etanercept. The agents appear to be well tolerated, but are significantly immunosuppressive and may be associated with increased risk of internal malignancy. While this is insufficient evidence to conclude that anti-TNF- $\alpha$  biologic agents are beneficial for the treatment of cutaneous sarcoidosis, these reports suggest that biological anti-TNF- $\alpha$  agents might be useful as an alternative or additional therapy, particularly in extremely recalcitrant cases. RCTs will therefore be necessary in order to evaluate fully their efficacy and long-term safety in patients with cutaneous sarcoidosis. It should be noted that one prospective trial evaluating etanercept for pulmonary sarcoidosis was terminated due to excessive treatment failures and safety monitoring board conclusion that the risk/benefit ratio was insufficient to proceed with enrollment [128]; as a result of this and cases of TNF-inhibitor-induced granulomatous diseases [129], some physicians have stated that etanercept should generally not be used for sarcoidosis. Notably, there is an ongoing

randomized placebo-controlled study investigating the effect of adalimumab in cutaneous sarcoidosis (NCT00274352), and another to compare golimumab (a novel TNF inhibitor) or ustekinumab (an IL-12/23 inhibitor) with placebo (NCT00955279).

### Conclusions

A review of the available data on oral and systemic therapy in cutaneous sarcoidosis reveals a dearth of evidence-based medicine, underscoring the need for RCTs. Unfortunately, most RCTs have been performed on pulmonary or other organ disease with a scattering of them also looking at skin disease. However, these often have variable end points that are not standardized, and drawing conclusions concerning cutaneous sarcoidosis can be challenging. Although oral steroids have been “grandfathered in” as the first-line treatment, on the basis of many clinicians’ personal experiences with sarcoidosis, this therapy has not been formally evaluated or proven in appropriate clinical trials.

The reported evidence suggests that chloroquine or hydroxychloroquine, methotrexate, and thalidomide may be the most effective medications for the treatment of cutaneous sarcoidosis. All of these agents may represent a reasonable therapeutic option as an alternative or adjunct to oral steroids. Less-studied potential alternatives include biologic TNF- $\alpha$  inhibitors, mycophenolate mofetil, tetracyclines, allopurinol, FAEs, and apremilast. Agents such as azathioprine and cyclosporine lack any data in cutaneous sarcoidosis. While chlorambucil was reported in the 1990s to treat chronic multi-organ sarcoidosis, the drug’s side-effect profile limits its potential for cutaneous sarcoidosis [64].

Additional drugs reported as successful in case reports include tranilast, melatonin, clofazimine, mepacrine, levamisole, alefacept, colchicine, systemic tacrolimus, and mizoribine [130–140]. While less studied, biologic TNF- $\alpha$  inhibitors may represent a new era in evidenced-based medicine for cutaneous sarcoidosis, especially in recalcitrant cases, particularly lupus pernio.

### What are the effects of topical and physical therapeutic interventions in patients with cutaneous sarcoidosis?

#### Topical corticosteroids and intralesional injections

While topical corticosteroids and intralesional injections are often recommended as the first-line treatment for the cutaneous manifestations of sarcoidosis, owing to their anti-inflammatory properties [18,21,22,38], the evidence for their efficacy is scant and has been reported in case series and case reports [141–144].

#### Benefits

Recently, Jung and Roh demonstrated two of three patients with specific lesions of cutaneous sarcoidosis responded completely to intralesional injections of triamcinolone; however, no dosing regimen was described [36]. Yanardag *et al.* demonstrated improvement in seven patients treated with intralesional kenalog, though these patients were receiving concomitant oral corticosteroids [145]. There are scattered reports of single cases demonstrating response to varying doses of intralesional corticosteroids, ranging from 10 to 40 mg/mL injected at intervals from biweekly to monthly [146–148].

In a single case report, intralesional chloroquine was successfully used to treat one patient as well [149].

#### Harms

In general, topical or intralesional steroids may lead to hypopigmentation, skin atrophy, tachyphylaxis, or systemic absorption. No

major side effects have been reported in any of the above studies. Minimal bleeding from needle puncture and postinflammatory hypopigmentation and hyperpigmentation are additional risks of intralesional hydrocortisone injections [143,150].

#### **Comments/implications for clinical practice**

The articles published to date describe a limited number of patients with cutaneous sarcoidosis treated with intralesional injections or topical steroids. This is insufficient evidence to conclude that this therapy is beneficial for the treatment of cutaneous sarcoidosis. Large RCTs are therefore necessary to evaluate their efficacy and safety. However, many dermatologists still use these modalities as first-line therapy, owing to their general anti-inflammatory properties.

#### **Tacrolimus**

Topical tacrolimus, a novel immunosuppressive agent successfully used in atopic dermatitis, inhibits the production of TNF- $\alpha$  by T cells and macrophages, and inhibits hapten-induced production of Th1 cytokines by T cells [151]. Thus, it may suppress the formation of granulomas in cutaneous sarcoidosis.

#### **Benefits**

Katoh *et al.* reported on a 62-year-old woman with recalcitrant persistent sarcoidosis of the face that resolved after treatment with topical tacrolimus without any adverse effects [151]. Gutzmer *et al.* reported on a 56-year-old woman with recalcitrant cutaneous sarcoidosis of the face whose disease almost completely resolved after a 3-month course of topical tacrolimus [152]. Landers *et al.* reported almost complete resolution of persistent cutaneous sarcoidosis in an eyebrow tattoo of a 70-year-old woman after the addition of tacrolimus 0.1% ointment to oral prednisone [153]. Green noted partial resolution of a nasal lesion of sarcoidosis with tacrolimus ointment 0.1% bid for 3 months that failed initial topical steroids [154]. De Francesco *et al.* noted topical tacrolimus 0.1% twice daily cleared facial sarcoidosis lesions on the forehead after 3 months of use in a patient who had failed clobetasol ointment [155], and Vano-Galvan *et al.* reported a complete response to topical tacrolimus 0.1% twice daily in a lichenoid type of cutaneous sarcoid lesion after 2 months of treatment [156].

#### **Harms**

Topical tacrolimus appears to be a safe and well-tolerated medication, both in the six reported cases of cutaneous sarcoidosis and in more than 1.7 million patients, most with atopic dermatitis. The most common adverse effects are skin burning and pruritus. Topical tacrolimus is not associated with increased rates of infection or malignancy in comparison with topical steroids when used intermittently [157,158].

#### **Comments/implications for clinical practice**

The articles published to date describe six patients who were treated successfully with topical tacrolimus. This is insufficient evidence to conclude that this therapy is beneficial for the treatment of cutaneous sarcoidosis. Further RCTs will be necessary in order to evaluate the safety and efficacy of topical tacrolimus in cutaneous sarcoidosis.

#### **Photomedicine**

##### **Flashlamp pulsed-dye laser therapy**

Flashlamp pulsed-dye laser (fPDL) therapy has been used successfully in the treatment of port-wine stains and telangiectasias, where

it selectively ablates the dilated and inflamed vessels [159]. This mechanism forms the rationale for its use in lupus pernio, a disfiguring cutaneous manifestation of sarcoidosis.

**Benefits** There are no RCTs or systematic reviews of fPDL therapy in cutaneous sarcoidosis. Goodman and Alpern reported on a woman with a 5-year history of lupus pernio of the nose who responded to fPDL at an energy level of 7–8 J/cm<sup>2</sup>. The improvement induced by the laser was temporary; the erythema and papules returned 7 months after the first treatment and 6–15 months after the second treatment, but on both occasions responded again to laser therapy. She received three sessions altogether, without side effects (such as atrophy, scarring, or hypopigmentation) [159]. Cliff *et al.* reported on a patient with lupus pernio of the nose, who improved after six treatment sessions at 6-week intervals with fPDL at a setting of 5.6–7.3 J/cm<sup>2</sup>. A biopsy of her nose after treatment showed noncaseating sarcoid granulomas, leading the authors to conclude that laser therapy was effective in improving the appearance of the lesions, but not the underlying disease process [160]. Dosik and Ashinoff reported on a woman with a 3-year history of topical and intralesional steroid-resistant lupus pernio who responded successfully to fPDL at an energy of 7.25 J/cm<sup>2</sup>. The therapy was given for nine sessions at 1–2-month intervals [161]. Holzman *et al.* reported improvement in a child with scar sarcoidosis treated with pulsed dye laser at 7.6–7.8 J/cm<sup>2</sup> fluence after three treatments at 6-week intervals. The patient previously failed topical tacrolimus and intralesional steroids [162]. Roos *et al.* had success with minimal use of fPDL (6 J/cm<sup>2</sup> fluence) being successful for multiple lesions of cutaneous sarcoidosis in a single patient [163].

**Harms** There were no side effects of laser therapy in the above patients. However, laser treatment has been reported to exacerbate cutaneous sarcoidosis in one patient [164]. The inherent risks of fPDL include erythema, atrophy, scarring, dyspigmentation, and a risk of eye damage when appropriate protection is not provided.

**Comments/implications for clinical practice** The articles published to date describe experience with six patients with treatment-resistant chronic lupus pernio who were treated with fPDL, three of whom had a positive result. This is insufficient evidence to conclude that fPDL is beneficial in the treatment of cutaneous sarcoidosis. RCTs will be necessary for definitive proof.

#### **Other laser modalities**

**Benefits** Nonablative lasers, such as a Q-switched ruby laser, that have the capacity to target foreign material in sarcoid lesions may be effective in treating cutaneous sarcoid lesions where foreign material, such as a tattoo, may be the nidus of granuloma formation. Additionally, ablative modalities, such as carbon dioxide laser, may effectively remove granulomatous lesions.

Grema *et al.* reported successful resolution of recalcitrant scar sarcoidosis of the elbow and knees in a 50-year-old woman using a Q-switched ruby laser. The patient remained recurrence free for over 3 years. The affected areas also had traumatic tattoos from abrasions, and did not resolve after three previous treatments with pulsed-dye laser [165]. O'Donoghue and Barlow reported on three patients with significant improvement of disfiguring lupus pernio after treatment with a CO<sub>2</sub> laser. The sarcoid granulomas were debulked, and wound healing occurred after 4 weeks. Two of the patients remained disease free after therapy [166]. Stack *et al.*

reported successful resolution of recalcitrant lupus pernio in a 31-year-old African-American man after excision and fulguration with a CO<sub>2</sub> laser, followed with an intralesional steroid injection in the postoperative period. The site healed well, and the patient had no recurrence. He experienced no adverse effects [167]. Young *et al.* reported on two patients with long-standing recalcitrant lupus pernio who were successfully treated with CO<sub>2</sub> laser resurfacing [168]. Ekback and Molin reported complete healing of long-standing recalcitrant lupus pernio in a 57-year-old white woman after two treatments with a frequency-doubled Nd:YAG laser (532 nm, 50 ms, 12–16 J/cm<sup>2</sup>) 7 months apart. Side effects included slight erythema and swelling of the treated skin areas 1 day after treatment. The patient had not experienced a relapse at the 3-month follow-up [169]. Rosende *et al.* reported the use of intense pulsed light therapy (515–1200 nm at 45 J/cm<sup>2</sup> fluence) over 2 years for control of a patient's lupus pernio; that patient had previously failed to respond to intralesional steroids and systemic agents (hydroxychloroquine, methotrexate, and allopurinol) [170]. Hocar *et al.* reported the successful use of a KTP laser (13 J/m<sup>2</sup>, 22 J/m<sup>2</sup> fluence) in two patients with facial cutaneous sarcoidosis [171].

**Harms** No significant complications were noted in these reports, but the inherent risks of laser therapy (scarring, dyspigmentation, erythema, as well as exacerbation of sarcoidosis and other photodermatoses) should be considered.

**Comments/implications for clinical practice** The articles published to date describe one patient who was successfully treated with a Q-switched ruby laser, six patients who were successfully treated with a CO<sub>2</sub> laser, one patient who was treated successfully with a frequency-doubled Nd:YAG laser, and two with a KTP laser. This is insufficient evidence to conclude that either therapy is beneficial for the treatment of cutaneous sarcoidosis. Further RCTs will be necessary in order to evaluate the safety and efficacy of laser therapy in cutaneous sarcoidosis.

#### Ultraviolet A therapy

Ultraviolet A1 (UVA1, 340–440 nm) has many known immunomodulating and immunosuppressive effects that may be responsible for the therapeutic effect in cutaneous inflammatory diseases, such as atopic dermatitis, urticaria pigmentosa, and lichenoid graft-versus-host disease. Longwave UVA induces apoptosis in T cells. UVA1 irradiation, similar to ultraviolet B, has been shown to induce the expression of immunosuppressive cytokines in human keratinocytes, including TNF- $\alpha$  and IL-10 [172,173]. The immunosuppressive properties of UVA1 form the basis for its use in cutaneous sarcoidosis.

#### Benefits

Mahnke *et al.* reported the disappearance of nearly all lesions of generalized recalcitrant cutaneous sarcoidosis in an 82-year-old white female after 50 sessions of medium-dose UVA1. Treatment was started at four times per week with medium-dose UVA1 at 20 J/cm<sup>2</sup> for the first three treatment sessions and 40 J/cm<sup>2</sup> for the subsequent 12 sessions. The final dose of 60 J/cm<sup>2</sup> was given 35 times. The patient experienced no adverse effects during or after therapy [172]. Graefe *et al.* reported marked improvement of cutaneous sarcoidosis on the forehead in a 63-year-old white woman after 25 sessions of high-dose UVA1, starting with 20 J/cm<sup>2</sup> for 2 days, 50 J/cm<sup>2</sup> for 3 days, 90 J/cm<sup>2</sup> for 5 days, and finishing with the final dose of 130 J/cm<sup>2</sup> four times weekly. After 25 sessions, a total dose of

2460 J/cm<sup>2</sup> was administered. The patient had no adverse effects and did not relapse [173].

Additionally, Patterson and Fitzwater reported significant improvement of hypopigmented sarcoidosis of the face after 8 months of tri-weekly psoralen-UVA (PUVA) therapy [174]. Courtois *et al.* also noted improvement in a single patient with cutaneous sarcoidosis with PUVA as well [175]. Gleeson *et al.* reported treatment of sarcoidosis with psoralen topical gel and UVA phototherapy. Six patients were given methoxypsoralen-8 gel 0.005% followed by 0.2 J/cm<sup>2</sup> with 0.1–0.2 J/cm<sup>2</sup> based on tolerance to a maximum of 3.7 J/cm<sup>2</sup> in conjunction with prednisone or hydroxychloroquine. All patients had skin improvement, with three of six obtaining complete resolution [176].

#### Harms

The patients experienced no adverse effects during therapy, but the long-term effects of UVA, such as the carcinogenic effects of therapy, have to be considered.

#### Comments/implications for clinical practice

To date, only two patients successfully treated for cutaneous sarcoidosis with UVA1 and eight patients successfully treated with PUVA have been reported in the literature. This is insufficient evidence to recommend UVA1 or PUVA therapy for cutaneous sarcoidosis. RCTs are therefore necessary to evaluate the efficacy and safety of UVA1 and PUVA in cutaneous sarcoidosis.

#### Photodynamic therapy

Photodynamic therapy (PDT) with aminolevulinic acid (ALA) targets rapidly proliferating cells, leading to cytotoxic and immunomodulatory effects. PDT with topical ALA is currently approved for the treatment of actinic keratoses, but has also been used successfully to treat superficial basal cell carcinoma and Bowen's disease, as well as inflammatory conditions such as verrucae, scleroderma, and psoriasis [177]. The anti-inflammatory and immunomodulatory effects of PDT in skin form the rationale for its use in cutaneous sarcoidosis.

**Benefits** Karrer *et al.* reported the only use of PDT in cutaneous sarcoidosis [177]. A 3-month course of PDT with topical ALA produced complete resolution of recalcitrant cutaneous lesions that had persisted for 17 years in a 67-year-old white woman. Topical ALA 3% in a gel containing 40% dimethyl sulfoxide was applied, under occlusion with a light-impenetrant paper, to the affected areas for 6 h. Subsequently, the lesions were irradiated with an incoherent light source emitting wavelengths of 580–740 nm, with a light intensity of 40 mW/cm<sup>2</sup> and an energy density of 20 J/cm<sup>2</sup>. PDT was performed twice weekly for the first 8 weeks, followed by treatments once a week, for a total of 22 treatments in 3 months. Four weeks after the onset of therapy, the plaques flattened and faded. After 3 months, the skin lesions resolved completely, without the development of new lesions. A biopsy obtained from a former lesional site 4 months after therapy showed histologically normal skin. The patient was free of skin disease and visceral involvement 18 months after PDT. Wilsmann-Theis *et al.* reported resolution of auricular and periocular sarcoidosis lesions with application of methyl aminolevulinate for 3 h followed by broadband light (590–780 nm at 38 J/cm<sup>2</sup> for 20 min) for the auricular lesion and red light (630 nm at 37 J/cm<sup>2</sup> for 8 min) for the periocular lesions over eight treatment sessions. The patient was able to complete treatment, but the course was complicated by development of cutaneous erosion

and superinfection at the site [178]. Patterson treated a patient with a forehead plaque of sarcoidosis successfully with seven sessions of 5-ALA followed by a noncoherent light source (633 nm at 75 J/cm<sup>2</sup>) over a course of 16 months, noting minimal discomfort to the patient [179]. Penrose *et al.* used a 2-h application under occlusion of 20% 5-ALA followed by blue light (417 nm at 10 J/cm<sup>2</sup> for 16 min and 40 s) to resolve nasal sarcoidosis. The patient experienced some dyschromia and desquamation with treatments [180]. Hasegawa *et al.* used a 3-h application of 20% 5-aminolevulinic cream to facial sarcoidosis followed by intense pulsed light (640 nm at 22–24 J/cm<sup>2</sup>) which led to resolution with five sessions every 2 weeks [181].

**Harms** The adverse effects included a slight burning sensation during irradiation, followed by erythema and edema of the treated area, lasting for about 2 days. Slight hyperpigmentation of the treated area occurred after 2 weeks of treatment and persisted for about 3 months after the end of PDT [177]. In addition to dyschromia, Penrose *et al.* noted desquamation, while Wilsman-Theis *et al.* noted erosion with superinfection from their treatment modality [178,180].

**Comments/implications for clinical practice** To date, six patients with cutaneous sarcoidosis have been reported with a positive result to PDT. This is insufficient evidence to conclude that this therapy is beneficial for the treatment of cutaneous sarcoidosis. RCTs will therefore be necessary for definitive proof.

## Plastic surgery

### Benefits

There are no RCTs or systematic reviews of plastic surgery in the treatment of cutaneous sarcoidosis. In 1970, O'Brien described two patients successfully treated with plastic surgery for lupus pernio [182]. In 1984, Shaw *et al.* described a man with a 6-year history of treatment-resistant lupus pernio successfully treated with surgical excision and split skin grafting; the results remained good 2.5 years after surgery [183]. Collison *et al.* described a man with extensive ulcerative nodules of the lower extremities, which were resistant to topical/intralesional steroids, oral steroids, hydroxychloroquine, and methotrexate. He was treated with vigorous operative debridement and partial-thickness skin grafting. While the grafts were well accepted (80%), the patient developed new ulcerating nodules in previously uninvolved skin 2 months after surgery [184]. Streit *et al.* reported on a woman with widespread ulcerative cutaneous sarcoidosis who was treated with Apligraf (graft skin), a bilayered human skin equivalent, with good results [185]. Smith *et al.* reported a successful case of nasal resurfacing of lupus pernio by forehead flap rhinoplasty [186]. Preminger *et al.* reported one case of cutaneous nasal sarcoidosis that remained in remission at 7-year follow-up from surgical treatment [187]. Lesavoy *et al.* noted a case in which a simple and straightforward surgical approach to severe nasal deformity from sarcoidosis obtained excellent results [188].

### Harms

No complications were noted in the above studies. However, the inherent risks of general anesthesia and surgery (bleeding, scarring, postoperative infection) should be considered.

### Comments/implications for clinical practice

The above articles describe eight patients with treatment-resistant chronic lupus pernio who were treated with plastic surgery, all of whom had a positive result. This is insufficient evidence to conclude

that this therapy is beneficial in the treatment of cutaneous sarcoidosis.

## Conclusions

There is a lack of significant evidence-based data on topical and physical therapies for cutaneous sarcoidosis. There are no RCTs to prove that intralesional or topical steroids are effective in the treatment of cutaneous sarcoidosis. Intralesional and topical steroids, like oral steroids, have been accepted as first-line therapies on the basis of clinicians' experience, with no definitive dosage or duration of therapy identified. Topical tacrolimus, a nonsteroidal agent, has been reported as successful therapy in only six patients. The physical modalities of laser and plastic surgery, as well as UVA phototherapy and PDT, have been reported as successful in treatment-resistant cases and disfiguring nasal sarcoidosis, but larger studies are lacking. Phonophoresis is another potentially beneficial modality, but it has only been described in an isolated case report [189]. Radiation therapy has been used in limited cases [190,191].

## Acknowledgments

We would like to note the effort of Anne Hawke, MD, and Leonid Izikson, MD, PhD, on the previous versions of this chapter.

### Key points

- There are no RCTs of any therapy for the treatment of cutaneous sarcoidosis.
- In a review of the existing literature on nonsteroidal systemic therapies for cutaneous sarcoidosis, antimalarials, methotrexate, and thalidomide appear to show clinical benefit, and thus may represent a reasonable therapeutic option in patients requiring an additional or alternative therapy. Other medications, such as biologic TNF inhibitors, tetracyclines, allopurinol, FAE, leflunomide, and apremilast require additional study, but could be used in difficult or resistant cases.
- A review of the existing literature on topical and physical therapies for cutaneous sarcoidosis shows that no therapy has been proven effective in controlled trials. However, the use of topical and intralesional corticosteroids, topical tacrolimus, photodynamic therapy, lasers, and plastic surgery could be used in certain clinical situations.

## CHAPTER 67

# Erythema multiforme

Pierre-Dominique Ghislain and Jean-Claude Roujeau

Department of Dermatology, Referral Center for Toxic and Autoimmune Blistering Diseases, Assistance Publique–Hôpitaux de Paris (APHP), Université–Paris-Est Créteil Val de Marne (UPEC), Henri-Mondor Hospital, Créteil, Cedex, France

## Background

### Definition

Erythema multiforme (EM) is an acute, febrile, self-limited, eruption characterized by target cutaneous lesions, with a symmetric and mainly acral distribution. Lesions are annular, with three zones: a central area of dusky erythema, sometimes bullous, a middle paler zone of edema, and an outer ring of erythema with a well-defined edge. Face and limbs, especially hands and feet, are the most commonly affected areas and are sometimes selectively involved. Mucous membrane erosions are frequent and define EM major or majus (EMM), compared with EM minor which lacks mucous membrane involvement. Histopathological examination typically shows an interface infiltrate and limited epidermal necrosis that affects mainly the basal layer. Some confusion persists in terminology and in the boundaries between EMM, Stevens–Johnson syndrome, and “EM-like” drug eruptions.

### Incidence

Unknown. For cases severe enough to require hospitalization: 1–6 per million per year.

### Etiology/risk factors

The principal cause is infection with herpes simplex virus (HSV), which probably accounts for 40–60% of all cases in adults. Many other infections can induce occasional cases, especially *Mycoplasma pneumoniae* infection, which is the leading cause in many pediatric series.

### Prognosis

EM has low morbidity and no mortality. Spontaneous resolution comes in 1–6 weeks. Sequelae are rare, but mucous membranes, including eyes and bronchial tract, may be affected in severe cases of EMM. Recurrences are frequent (at least 30%). Rarely recurrences overlap, leading to “continuous” or “persistent” EM. Mouth erosions may strongly impair the quality of life of patients.

### Aims

To reduce the duration of fever, eruption, and hospitalization; and to prevent or reduce recurrences.

### Outcomes

Duration of fever, eruption and hospitalization; frequency of recurrences; number of days with symptoms per year.

### Methods

*Clinical Evidence* search and appraisal October 2012 (Cochrane databases of randomized controlled trials (RCTs) and controlled clinical trials, Medline 1966 to October 2012).

We found one brief “evidence-based” review on corticosteroids [1] and six randomized clinical trials, all on a small number of patients and most raising concerns on methodological issues [2–7].

## Questions

### What are the effects of treatment of acute attack?

#### Short course of systemic corticosteroids

Based on a retrospective series or small RCT, corticosteroids seem to shorten the duration of fever and eruption but to increase length of hospitalization because of the risk of complication. There is no evidence that patients with EM benefit from corticosteroids.

#### Benefits

Sixteen children with EMM were included in a randomized controlled prospective study within 3 days from the onset of rash; 10 received bolus infusions of methylprednisolone (4 mg/kg per day) while six had only supportive treatment (in a different center). Corticosteroids allowed a significant reduction of the period of fever (4.0 vs 9.5 days), but not a significant reduction of the period of acute eruption (7.0 vs 9.8 days) and milder signs of prostration. Complications were minimal in both groups [7].

**Harms**

An RCT included nine adult patients with mild, uncomplicated EMM; four received prednisolone and five received placebo. The mean length of stay in hospital was longer in the corticosteroid group (9.5 vs 8 days). But diagnoses were not clear: histology was consistent with EM; a drug was suspected in five cases; and no information about HSV was given [5].

In a retrospective study, Rasmussen compared 17 children with EM treated by systemic corticosteroids with 15 children with supportive care only. Both groups were comparable in age, sex, length of prodroms, exposure to drugs, initial fever, extent of oral and cutaneous involvement, and frequency of isolation of pathogens. The group with corticosteroids had a shorter fever period (1.8 vs 5.5 days) but a longer mean length of hospitalization (21 vs 13 days), because of more frequent complications (53% vs 0%) [8].

In a series of 51 children, corticosteroids were claimed to worsen the prognosis: the patients treated with corticosteroids had 74% of complications, versus 28% for the patients without corticosteroids [9].

In a series of 25 patients with EM minor, corticosteroids allowed no clinical improvement except a shorter duration of fever (2.7 vs 5.6 days) [4].

**Comment**

The usefulness of corticosteroids seems to be limited, and side effects are frequent. However, the methodology of most studies was poor, with small numbers, and a mix of idiopathic or viral-associated EM and drug-induced Stevens–Johnson syndrome.

**Erythromycin**

We found no evidence on usefulness of erythromycin.

**Benefits**

We found no evidence.

**Harms**

We found no evidence.

**Comment**

Erythromycin or related antibiotics are claimed to be potentially useful only when *Mycoplasma pneumoniae* infection is suspected. There is no evidence to support that treating the infection has a beneficial effect on the course of EM.

**Acyclovir**

We found no RCT. In several series it was reported that initiating acyclovir for the treatment of full-blown post-herpetic EM was useless.

**Benefits**

We found no evidence.

**Harms**

We found no evidence.

**Comment**

Probably useless (strength of recommendation C; recommendation based on consensus, usual practice, opinion, disease-oriented evidence, or case series for studies of diagnosis, treatment, prevention, or screening).

**What are the effects of treatment to prevent recurrence?****Sun protection**

We found some indirect evidence on possible benefit of sun protection.

**Benefits**

Ultraviolet A may induce herpes recurrence. We found some evidence that sunscreen protection prevents herpes recurrence (strength of recommendation B?) [10]. We found no data on possible effect on recurrent EM.

**Acyclovir**

We found one RCT, on the effectiveness of continuous oral acyclovir to prevent EM recurrences.

**Benefits**

We found one RCT: 19 patients with more than four attacks of EM per year were enrolled in a 6-month double-blind, placebo-controlled trial of acyclovir 400 mg twice daily. Median number of attacks in the acyclovir group was zero (0–2) compared with three (1–6) in the placebo group (significantly different). At inclusion time, five patients had not clinical evidence of disease precipitation by HSV; two of them were in the acyclovir group; one showed complete disease suppression [6].

A prior RCT had observed no efficacy from topical acyclovir at the site of recurrent herpes [3].

**Harms**

We found no evidence.

**Comment**

Continuous oral acyclovir is effective to prevent recurrences of herpes-associated EM, but it may also be useful in some patients without clinical evidence that herpes is the precipitating factor (strength of recommendation B).

Valaciclovir and famciclovir have not been evaluated in formal trials but series suggested that they are able to prevent recurrences, likely as well as acyclovir [11] (strength of recommendation C).

**Levamisole**

In one RCT, levamisole appeared useful.

**Benefits**

We found a double-blind, placebo-controlled crossover trial, which included 14 patients with chronic or recurrent EM resistant to corticosteroids. Dose of levamisole was 150 mg/day for three consecutive days each week, for at least 4 weeks after first appearance of a lesion. Levamisole allowed decrease of severity, duration, and frequency of EM attacks [2].

An open comparative trial showed similar efficacy of levamisole used alone (17 patients; 76% of complete response) versus prednisone–levamisole combination (22 patients; 82% of complete response) [12].

**Harms**

Because agranulocytosis is a severe and not exceptional adverse effect, levamisole is not approved by most drug agencies.

**Comment**

The benefit–risk balance does not support the use of levamisole in EM (strength of recommendation C).

### Azathioprine, mycophenolate mofetil

We found several case series reporting benefit of azathioprine.

#### Benefits

We found no controlled trial.

In a series of 65 patients with recurrent EM, 11 were treated by azathioprine, when all other treatments had failed. Azathioprine was successfully used in all 11 patients [13]. Another case series reported five cases [14].

In a series of 48 cases both azathioprine and mycophenolate mofetil were reported to induce complete or partial remissions [11].

#### Harms

No evidence of harm was reported in these case series. Most immunosuppressive agents are associated with increased susceptibility to infection and with the development of malignancies. Baseline erythrocyte thiopurine methyltransferase levels should be checked prior to initiating treatment with azathioprine. Blood counts and liver function should be carefully monitored. Mycophenolate mofetil commonly causes gastrointestinal symptoms and has been rarely reported to cause lymphoma and recently multifocal leukoencephalopathy.

#### Other agents

We found no controlled trials.

Series reported benefits from dapsone, hydroxychloroquine, intravenous immunoglobulin, potassium iodide, or thalidomide [11,15].

### What are the effects of treatments on “continuous” or “persistent” forms?

#### Thalidomide

We found one case series on the benefit of thalidomide in EM.

#### Benefits

We found one retrospective analysis of thalidomide prescriptions (1981–1993), which showed efficacy for treatment of recurrent or “continuous” EM [16]. These data were uncontrolled and only supported by further case reports.

#### Harms

We found no evidence, but well-known severe side effects of thalidomide, especially teratogenicity and toxicity to nerves, deserve careful attention.

#### Comment

Likely useful, based on clinical “expert opinion” only (strength of recommendation C).

### Key points

- We found one RCT, which provided evidence for the usefulness of acyclovir to prevent EM recurrences (strength of recommendation B; recommendation based on inconsistent or limited-quality patient-oriented evidence).
- We found no evidence on usefulness of systemic corticosteroids in treatment of acute attack of EM.
- We found no good evidence on all other therapeutic choices.

### Interventions

#### Beneficial

- Systemic acyclovir to prevent recurrence.

#### Trade-off between benefits and harms

- Levamisole, thalidomide.

#### Unknown effectiveness

- Antimalarials, azathioprine, dapsone, mycophenolate mofetil, potassium iodide.

# Stevens–Johnson syndrome and toxic epidermal necrolysis

Jean-Claude Roujeau, Pierre-Dominique Ghislain, and Laurence Valleyrie-Allanore

Department of Dermatology, Referral Center for Toxic and Autoimmune Blistering Diseases, Assistance Publique–Hôpitaux de Paris (APHP), Université–Paris-Est Créteil Val de Marne (UPEC), Henri-Mondor Hospital, Créteil, Cedex, France

## Background

### Definition

The definitions proposed by the “consensus of experts” in 1993 [1] were more or less clearly accepted worldwide. According to these definitions, Stevens–Johnson syndrome (SJS) and toxic epidermal necrolysis (TEN) are variants of the same process, presenting as severe mucosal erosions with widespread purple cutaneous macules (or “atypical targets”), often confluent with a positive Nikolsky sign and epidermal detachment. In SJS, epidermal detachment involves less than 10% of total body skin area; transitional SJS–TEN is defined by an epidermal detachment between 10 and 29% and TEN by a detachment of 30% or more. Full-thickness epidermal necrosis is observed on pathological examination. The skin biopsy and occasionally a direct immunofluorescence test are necessary to exclude alternative diagnoses of diseases that may resemble SJS/TEN. No laboratory test or imaging technique is needed for the diagnosis, but many are needed for evaluation of complications and occasionally for determination of causality.

### Incidence

Based on cases registries and observational studies, the incidence of TEN is estimated to 1–1.4 cases per million inhabitants per year. The incidence of SJS is probably of the same order (1–2 cases per million inhabitants per year) [2–4].

Women are overrepresented among adult cases, whereas the sex ratio is equal in childhood. The incidence increases after 40 years of age.

### Etiology/risk factors

SJS/TEN is predominantly drug induced (70–80% of cases). Graft-versus-host disease is another well-established but rare cause, independent of drugs. A few cases are related to infections (*Mycoplasma*

*pneumoniae*); other cases remain unexplained (“idiopathic” forms). The most extensive studies of medication use and SJS/TEN mainly pointed to allopurinol, many anticonvulsants (lamotrigine, carbamazepine, phenytoin, phenobarbital), anti-infectious sulfonamides, and some nonsteroidal anti-inflammatory drugs [5,6]. Human immunodeficiency virus infection, “collagen-vascular diseases,” especially systemic lupus, active cancer, and radiotherapy increase the risk [5,6]. A genetic susceptibility human leukocyte antigen (HLA)-linked has been demonstrated for a few drugs, varying with ethnicity (see later).

### Prognosis

SJS/TEN is an acute, self-limited disease, but with high morbidity and nearly constant sequelae. Mortality rates at 3 months are 10–15% with SJS, 40–50% with TEN, and 30–35% with transitional forms [7]. Epidermal detachment may be extensive and may extend to the entire skin surface in the most severe cases. As in severe burns, fluid losses are massive and electrolyte imbalance common. Super-infection, thermoregulation impairment, energy expenditure, alteration of immunologic functions, and hematologic abnormalities are usual systemic complications. Mucous membrane involvement (oropharynx, eyes, genitalia, and anus) require attentive nursing. Gastrointestinal and tracheobronchial epithelium can be also involved and cause high morbidity.

Age, recent malignancy, percentage of denuded skin, neutropenia, serum urea nitrogen level, and visceral involvement are prognosis factors. SCORTEN, a SJS/TEN-specific scoring system for vital prognosis estimation, has been proposed [8]. SCORTEN has been validated in many centers [9–15].

After healing of the acute phase (3–6 weeks), nearly all patients suffer from one or several sequelae that alter their quality of life and may be severely invalidating. They include pigmentation disorders, scars on skin, synechiae and dryness of mucous membranes of the

mouth and genitalia, posttraumatic stress, and many others. The most severe are ocular lesions that may progress and lead to blindness [13].

### Aims of treatment

- *In the acute stage:* to reduce mortality, to limit the extent of the disease, to reduce associated morbidity, and to prevent sequelae.
- *In the long term:* to detect and manage sequelae, to evaluate drug causality, and to advise the patient on future utilization of medicines.

### Outcomes

In a disease of such severity the primary outcome is obviously *mortality rate*; secondary outcomes include percentage of epidermal detachment at the acme of the disease, infectious complications, length of healing, length of stay in hospital, and sequelae.

### Methods

For search and appraisal we used the Cochrane Library and Medline 1966 to June 2012. We found:

- Three systematic reviews of “specific” treatments [16–18].
- Thirteen randomized controlled trials (RCTs):
  - seven that only mentioned the occurrence of SJS/TEN as a side effect during an RCT (not analyzed);
  - one evaluating corticosteroids in erythema multiforme (not analyzed);
  - one specifically evaluated treatment of SJS/TEN with thalidomide [19];
  - four addressed the treatment of ocular lesions caused by a variety of diseases; all included a minority of SJS/TEN cases [20–23].
- Two treatment recommendations based on adequate methodology [24,25].
- One large observational study (cohort) [7].

## Questions

### Is it possible to prevent Stevens–Johnson syndrome/toxic epidermal necrolysis?

#### Pharmacogenetics approach

In the past 10 years many studies have addressed the possible genetic basis of severe adverse drug reactions, and especially SJS/TEN. A Taiwanese group first reported a 100% association between SJS/TEN induced by carbamazepine and HLA-B\*15:02 [26] and also a 100% association of SJS/TEN induced by allopurinol and HLA-B\*58:01 [27]. Many further studies were done, and 2012 knowledge on HLA as possible marker of SJS/TEN can be summarized as follows:

- A strong association of carbamazepine-related SJS/TEN to HLA-B\*15:02 was found only in Asian countries where this allele has a high prevalence (China, Singapore, Thailand, Vietnam, India, etc.), but not in Japan, Korea, or Europe [28].
- The association of HLA-B\*58:01 and SJS/TEN related to allopurinol is found worldwide but is much less strong than in South East Asia [28].
- In Han Chinese, HLA-B\*15:02 is also a risk factor for induction of SJS/TEN by other “aromatic” anticonvulsants (phenytoin,

oxcarbazepine, lamotrigine). The association is weaker than for carbamazepine, however [29].

- Even in Taiwan, most persons with the HLA-B\*15:02 allele do not develop SJS/TEN when treated with carbamazepine, probably because the reaction of the immune system also requires specific allele(s) in the repertoire of T lymphocytes [30].
- No other association strong enough to be useful as a predictive test has been detected [31].

A large cohort study has demonstrated the absence of SJS/TEN in 4505 Taiwanese patients who tested negative for HLA-B\*15:02 and were treated with carbamazepine [32]. *That study is the first evidence that SJS/TEN can be prevented by a pharmacogenetics approach.*

Based on the above evidence, drug agencies in USA (Food and Drug Administration) and Europe (European Medicines Agency) have issued the recommendation that “patients originating from areas where HLA-B\*15:02 is prevalent [China and South East Asia] should be offered a test for that allele before being treated with carbamazepine.”

In patients positive for HLA-B\*15:02 it is also logical to avoid all “aromatic anticonvulsants” as alternatives to carbamazepine. Testing patients from South East Asia for HLA-B\*58:01 before prescribing allopurinol also seems logical [33], even though no recommendation has been issued yet by drug agencies. Although knowledge on the genetics of SJS/TEN is still limited, it appears also prudent to avoid the “culprit” drug in first-degree relatives of a patient who developed SJS or TEN.

### Avoiding prescription of “strongly associated” medications that lack evidence of usefulness

Some medications “strongly associated” with the development of SJS/TEN are too often prescribed without an evidence-based rationale. For example, there is no evidence that prophylactic anticonvulsant therapy decreases the incidence of seizures in patients with brain tumor and no history of seizures [34], a practice that is associated with many cases of SJS/TEN related to anticonvulsants [6]. There are persistent controversies on potential benefits of allopurinol use in patients with asymptomatic hyperuricemia, which was the reason for prescription in a majority of patients with allopurinol-related SJS/TEN in Europe [35].

### What are the effects of prompt withdrawal of potential culprit drug(s)?

We found limited evidence that early withdrawal of the drugs that cause SJS/TEN improves the prognosis of the disease.

#### Benefits

One observational study, showed that death rates were lower when causative drugs with short elimination half-lives were withdrawn no later than the day when blisters or erosions first occurred: 2/44 (5%) versus 11/42 (26%). No difference was seen for drugs with long half-lives [36].

#### Harms

We found no data.

#### Comment

Since it would be unethical to perform an RCT of the effect of prolonging drug administration, observational studies will remain the only available clinical evidence for this question.

In addition to immediate discontinuation of suspected drug(s), stopping concomitant medications that are known for impairing

the metabolism or excretion of the suspect drug should be considered.

Discontinuation of other non-suspected important medications should be avoided (experts' recommendation [25]).

### Are there any specific treatments?

The mechanism leading to apoptosis of the epidermis and mucous membranes epithelium in SJS/TEN has been suspected for years to involve the immune system but was elucidated more precisely in the past few years. Basically, it involves drug-specific cytotoxic T-cells and nonspecific cytotoxic cells that release cytolytic cytokines, especially granulysin [37].

A long list of medications/methods expected to have an immunosuppressive or immunomodulating effect were proposed (e.g., corticosteroids, cyclophosphamide, plasmapheresis, thalidomide, *N*-acetylcysteine, intravenous human immunoglobulins (IVIGs), cyclosporine A, and anti-TNF monoclonal antibodies). We will only discuss here those that were submitted to some evaluation: thalidomide (RCT), IVIGs (meta-analyses, cohort), corticosteroids (meta-analyses, cohort), cyclosporine A (comparison of observed mortality with mortality predicted by SCORTEN).

### Thalidomide

We found one RCT versus placebo, which shows an excess of mortality with thalidomide.

Thalidomide has been proposed as treatment of TEN because it is a potent inhibitor of TNF- $\alpha$  action.

### Benefits

We found no clinical evidence about benefits of thalidomide use in TEN/SJS.

### Harms

We found a double-blind, randomized, placebo-controlled study of thalidomide in TEN [19]. The regimen was a 5-day course of thalidomide 400 mg daily. Twenty-two patients were included, but the study was stopped because there was an unexplained excess of mortality in the thalidomide group (10 of 12 patients died, compared with 3 of 10 in the placebo group). There was no significant difference in origin of death between both groups [19].

### Comment

Based on a unique RCT, thalidomide should not be used in TEN.

### Intravenous immunoglobulins

Using IVIGs for SJS/TEN was proposed in 1998 [38] based on the hypothesis that Fas ligand (FasL) was the main mediator of widespread keratinocyte apoptosis in TEN and on the finding that high-dose IVIGs were able to antagonize FasL effects. More recent studies refuted an important role of FasL [39–41], invalidating the initial rationale for using IVIGs.

We found no good evidence on the effects on IVIGs in SJS/TEN, but available data do not suggest efficacy.

We found three "systematic reviews" [16–18].

- 1 Del Pozzo-Magana *et al.* [17]. The authors included 31 publications: 18 case reports (one to four cases), six prospective "cohorts" (2–10 cases), six retrospective "cohorts" (7–17 cases), and one "pseudo-randomized" study of erythema multiforme major (16 cases). "Cohort" studies adhered poorly to STROBE recommendations. Outcome measures were time to objective response (lack of fever), to remission (undefined), and length of hospital stay. Results are presented in a table as range of means of the

three time measures and many missing values by four treatment groups: IVIGs, corticosteroids, dressings, supportive care only. Based on a longer time to absence of fever (mean 9.5 days in a single study vs range of means 1–4 days) and to complete remission (7–22 vs 4–18 days), the authors conclude that supportive care alone is the "worst option" and that IVIGs or corticosteroids can be recommended. They do not discuss the nonspecific effect of corticosteroids on fever and the mild "difference" in time to complete remission. Poor quality and heterogeneity of reports did not allow any statistical analysis.

- 2 Roujeau and Bastuji-Garin [16]. This paper is another systematic review far from being perfect. Authors gathered all 47 series including at least 10 cases of SJS/TEN treated with any of the three following regimens: supportive care only, corticosteroids only, IVIGs only. Among these, all 13 containing a clear description of treatment(s) and an evaluation of SCORTEN were analyzed, allowing calculation for each series of a mortality ratio (MR: actual mortality/mortality predicted by SCORTEN) and a pooled MR with 95% confidence interval (CI) for each treatment. The series analyzed comprised a total of 439 patients. Supportive care only was used in 199 with a pooled MR of 0.89 (95% CI, 0.67–1.16;  $P = 0.43$ ) and IGIVs in 162 with a pooled MR of 0.82 (95% CI, 0.58–1.12;  $P = 0.23$ ).

These results suggested that SCORTEN slightly overestimated the risk of dying in both groups without any difference related to treatment.

- 3 Huang *et al.* [18]. This paper is far from being perfect because, in the absence of any RCT, the authors included what they called "observational controlled" series with at least eight cases of TEN or SJS–TEN overlap treated with IVIGs and compared with an historical group or comparing observed mortality with mortality predicted by the SCORTEN. A major difference with prior compilations of series [42] was effort to eliminate duplicate cases. They finally analyzed 17 studies including 113 patients treated with IVIGs and 130 treated with supportive measures only. The two groups were similar in ages and distribution of TEN versus overlap cases. The pooled odds ratio (OR) for mortality in patients treated with IVIGs was 1.00 (95% CI, 0.58–1.75). The authors also performed subgroup analyses that they interpreted as indicating a trend that higher doses of IVIGs might be better than low doses in adults and that IVIGs might be effective in children. Based on very low numbers, the later conclusion is highly debatable.

We found one European cohort study (EuroSCAR) [7]. A limitation is that an unknown number of patients had been likely included in series reporting the effect of a treatment in a few participating centers (IVIGs). The cohort included 281 patients, 87 received supportive treatment only, 35 IVIGs only, and 40 IVIGs and corticosteroids. Mortality did not differ between treatment groups, with no trend for a benefit from IVIGs (OR, 1.6; 95% CI, 0.6–4.3) compared with supportive care.

### Corticosteroids

We found no good evidence about corticosteroids use in SJS/TEN. Beneficial effects are doubtful.

We found two meta-analyses [16,17] and one cohort study [6], all also addressing the possible benefit of IVIGs. The first meta-analysis of pediatric cases suggested some debatable benefit on a shorter course of disease. The second meta-analysis included all series published up to December 2009 with at least 10 patients and using SCORTEN to compare actual with predicted mortality.

The pooled MR for 78 patients treated with corticosteroids was 0.92 (95% CI, 0.53–1.48), compared with 0.89 (95% CI, 0.68–1.16) for 199 patients with supportive care. That result does not suggest a substantial benefit.

The cohort included 281 patients. In the 119 who had received corticosteroids only, there was a trend towards a decreased mortality compared with supportive care that did not reach statistical significance (OR, 0.4; 95% CI, 0.2–1.1).

Many TEN cases have occurred during treatment by corticosteroids for preexistent disease. The possible impact on development of SJS/TEN was evaluated by three studies. The data of 216 patients with TEN were investigated in a retrospective study; 11 of them had been treated with corticosteroids for at least a week prior to the first sign of TEN (from 1 week to several months, at dosage between 7.5 and 325 mg prednisolone per day) [43]. In another series of 179 patients, 13 were undergoing long-term glucocorticosteroid therapy before TEN. Compared with 166 other cases, these patients had a longer delay between the introduction of the suspect drug and the onset of TEN, and a longer time elapsed between the first symptom of TEN and hospital admission. No other differences were observed [44].

Recently, a case-control analysis was done on the database of EuroSCAR and RegiSCAR studies comparing 92 patients with prior exposure to corticosteroids before the onset of SJS/TEN to 321 patients without prior exposure. In patients receiving corticosteroids the onset of disease after initiation of inducing drug was delayed by 7.1 days (95% CI, 0.2–4.5), disease progression was longer by 2.2 days (95% CI, 1.1–3.2), but disease severity and mortality were not affected [45].

#### Comment

These three studies of systemic corticosteroids use before onset of SJS/TEN obtained similar results, suggesting that corticosteroids have some impact on the progression of the disease, while strangely not modifying its final severity and mortality.

### Cyclosporine A

We found no sufficient evidence on effects of cyclosporine.

#### Benefits

We found several case reports and two case series of TEN treated with cyclosporine A.

In the first series of 11 cases of TEN [46], the treatment was safe and was associated with a more rapid re-epithelialization rate and a lower mortality rate (0/11 vs 3/6) in comparison with a historical series of patients treated with cyclophosphamide and corticosteroid.

The second series [47] included 29 patients with SJS or TEN treated with cyclosporine (3 mg/kg per day). None died when the SCORTEN predicted three deaths (no significant difference). Progression of disease was less frequent than among historical controls.

#### Harms

No serious side effects were reported in the first series [46] and three were reported in the second (reversible leukoencephalopathy, severe neutropenia, nosocomial pneumonitis) [47].

#### Comment

These results suggest that further studies should be conducted to evaluate the possible effectiveness of cyclosporine.

Conclusions on specific treatments (endorsed by recommendations issued in USA [24] and in France [25]):

- Available evidence does not allow recommending any “specific” treatment.
- Adequate supportive care is the priority in management of SJS/TEN.

### What are the effects of symptomatic treatments?

Most, but not all, of the symptomatic treatments for SJS/TEN are the same as those for severe burns. Some are based on evidence obtained in burns and/or in patients treated in intensive-care settings. We found no controlled study of supportive care for SJS/TEN.

Major components of symptomatic treatment include: (expert recommendations) [24,25]:

- Careful handling, strict asepsis.
- Warming of environmental temperature.
- Control of pain with liberal use of morphine or related agents.
- Intravenous fluid replacement (quantity adjusted daily) by venous lines as distant as possible from affected areas, with formulas decreased by at least one-third from formulas proposed for burns.
- Control of frequent hyperglycemia.
- Continuous enteral nutrition (by nasogastric tube).
- Local care of skin using antiseptics and nonadhesive dressings.
- Irrigation, emollients, antiseptic solutions without preservatives many times daily of affected mucous membranes; mechanical disruption of adhesions.
- Prophylactic use of antibiotics is *not* recommended.
- Repeated bacteriological sampling of skin, blood, urine, and site of intravenous lines.

Debridement of necrotic epidermis is highly controversial:

- Stripping of all “detachable” epidermis under general anesthesia is still performed in many burn units and recommended by some US experts [24]. That practice is based on an old RCT that demonstrated a benefit on survival for adult patients with *burns* of mixed thickness [48].
- If stripping is done, it must be followed with adequate coverage (porcine xenografts, cadaveric allografts, silver sulfadiazine/gauze dressings, amniotic membranes, cultured keratinocytes, synthetic dressings). Many RCTs compared these different dressings and suggested benefits for amniotic membranes or synthetic dressing versus conventional silver-sulfadiazine-impregnated gauze [49–53].
- In SJS/TEN, the level of epidermal detachment is equivalent to superficial burns (thickness I or IIa) and a growing number of burn units are using “anti-shear” therapy instead of stripping [54,55].

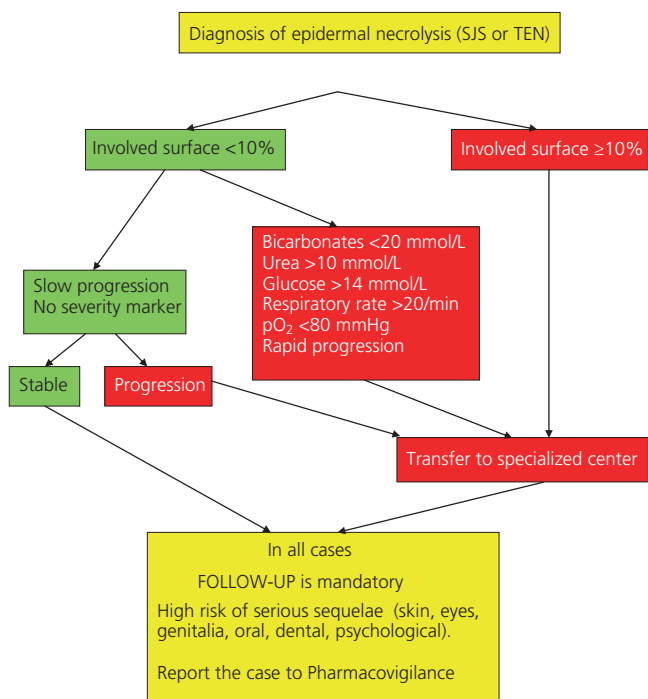

#### Comment

The supportive measures described above require specialized nurses and physicians (multidisciplinary team) and access to life-supporting resources such as mechanical ventilation, dialysis, and anesthesia.

### Is there a policy for referral to specialized medical units?

We found several large retrospective series that observed a lower risk of infection and a lower mortality if patients were referred early to a specialized unit [9,13,56–58].

None of these studies discussed a possible selection bias; that is, milder cases being less likely to be transferred. Most, anyhow, were

**Figure 68.1** Decisional tree for transfer of patients with SJS or TEN. We thank the French Haute Autorité de Santé (HAS) for allowing the translation from the original figure published within the Plan National de Diagnostic et de Soins “Nécrolyse épidermique toxique (Syndromes de Stevens-Johnson et de Lyell) – Juin 2010.” The HAS denies any responsibility for errors or omissions resulting from translation. For the original text, see Ref [25].

based on multivariate analyses, including factors known to impact the prognosis.

### Comment

Even if current evidence is far from being perfect, it suggests that delayed transfer is harmful.

Recommendations issued by experts in the USA and France consider that early referral to a specialized unit is a priority [24,25]. A decisional algorithm for referral was proposed in the French recommendations (Figure 68.1) [25].

### Evaluation of drug causality: are Stevens–Johnson syndrome/toxic epidermal necrolysis always drug induced?

Twenty years ago it was often stated that TEN was always drug induced while SJS could be induced by drugs or by infections [59]. Both parts of this assertion have proved erroneous with increasing knowledge. In the SCAR case–control study the etiologic fractions for significantly associated medications were 64%, 66%, and 65% for SJS, overlap SJS–TEN, and TEN respectively [60]. These were underestimates, since the statistical power was insufficient to prove an association for a few rarely used drugs, when found in a few cases and no control, but it was also unlikely that the etiologic fraction might increase to more than 80% with much larger studies. With further large studies looking for individual causality, a prob-

able or very probable drug cause was found in 62% of cases, and a possible drug cause in 23%. Fifteen percent of patients had been exposed either to no medication at all (2%) or only to medications with unlikely or very unlikely causality (13%) [61]. The very rare cases with a documented alternative etiology (acute graft-versus-host disease, *Mycoplasma pneumoniae* infection) explain a very small fraction of cases; others remain “idiopathic.”

### Is there any test to prove drug causality?

We found no evidence for a reliable test to prove the link between a single case and a specific drug.

### Benefits

A few studies about patch tests in SJS/TEN cases suggested a rather low sensitivity (10–60%), but probably good specificity, suggesting that they may help in assessing causality in some difficult cases [62,63].

We found only case reports and no clinical trial about in vitro tests (i.e., lymphocyte transformation tests) [64,65].

### Harms

No reactivation of SJS/TEN was reported from patch tests. We found only a few case reports of generalized erythema or irritation.

### Comment

Sensitivity and specificity of patch tests – and thus their clinical usefulness – need further evaluation, but available data suggest low sensitivity. The same conclusion also applies to available in vitro tests.

### Usefulness of algorithms for drug causality

Many methods have been proposed to determine causality of adverse drug reactions [66,67]. A specific algorithm (ALDEN) has been elaborated for SJS/TEN and showed an acceptable correlation with the results of case–control analyses and better performances than a general algorithm applying to all types of reactions [61].

### Benefits

ALDEN provides a better discrimination of “probable/very probable” and unlikely/very unlikely causative medications, allowing better counseling on future use of medications.

### Harms

We found no study of harm that may result from erroneous determination of causality.

### Is a follow-up needed?

Several hundred case reports focused on the many possible sequelae of SJS/TEN and their potential severity. Two cohort studies [13,68] demonstrated that sequelae were much more frequent than previously suspected, affecting more than 90% of patients surviving at 1 year. In addition, late and evolving eye lesions can be detected later in patients without apparent initial ocular involvement.

Given the high prevalence, possible late onset, and possible severity of sequelae, expert recommendations [25] are:

- to inform patients and their physicians of the risks;
- to schedule follow-up examinations and referral to organ specialists as needed.

Only ocular sequelae were the topic of therapeutic studies, including a few RCTs [20–23]. Unfortunately, most patients

included in these RCTs had ocular lesions of other causes and likely different mechanisms, allowing no conclusion specifically related to SJS/TEN.

### Possible benefits

We found two open trials of gas-permeable scleral contact lenses in patients with ocular surface lesions resulting from SJS/TEN that suggested an important improvement of pain, photophobia, vision, and quality of life [69,70].

### Comment

The high prevalence of long-lasting sequelae means that SJS/TEN should be considered not only an acute life-threatening event but also a chronic debilitating disease. Efforts should be directed to understanding the mechanisms of sequelae and designing and evaluating interventions aimed at their prevention and management.

### What happens in cases of rechallenge with the causative drug or a related drug?

We found no evidence on risk of reuse of culprit drug and on the possibility of desensitization in patients with TEN.

Large prospective cohorts of patients (SCAR, EuroSCAR, RegiSCAR) included a few patients who had a history of prior SJS or TEN always attributed to the same medication that was considered responsible for the recurrence. Even though an old series of oral reintroduction tests in TEN (10 cases) and SJS (eight cases) resulted in recurrence in only two cases [71], the risk for life is so high that avoiding the culprit drug and compounds closely related chemically is recommended [25].

There is no evidence to suggest that patients who have had SJS/TEN should avoid all “strongly associated” medications when not related to the one that induced their disease [25].

Some data are available for desensitization in benign cutaneous adverse drug reactions using escalating doses. Using such a protocol in a patient with a history of SJS or TEN could be considered acceptable only in the case of vital need and absence of alternative medication.

### Interventions

#### Found to be beneficial

- HLA testing prior to administration of “strongly associated” medications has a preventative role, but only for a few drugs and selected population groups.

#### Likely to be beneficial

- Avoiding prescription of “strongly associated” medications that lack evidence of usefulness.
- Prompt withdrawal of potentially causative drugs.
- Prompt referral to highly specialized center.
- Symptomatic treatments.

#### Unknown effectiveness

- Systemic corticosteroids, IVIGs, plasmapheresis, cyclosporine A.

#### Harmful

- Thalidomide.

### Key points

#### Prevention

- We found evidence that excluding patients harboring a specific HLA allele decreased the risk of carbamazepine-related SJS/TEN in Han Chinese. That exclusion probably applies also to other populations in South East Asia.
- We found evidence that some “strongly associated” medications are too often prescribed without evidence-based rationale (e.g., anticonvulsants for prevention of seizure in patients with brain tumors or allopurinol for asymptomatic hyperuricemia).

#### Specific treatments

- We found insufficient evidence about effective “specific” treatments.
- We found only one placebo-controlled RCT, which reported a higher mortality with thalidomide regimen.
- We found three systematic reviews and one large cohort study suggesting no benefit from using systemic corticosteroids or IVIGs in addition to symptomatic care.
- We found no good evidence on the effects of any other “specific treatment.”

#### Supportive care

- We found no evidence on the value of supportive care applying directly to SJS/TEN, but expert recommendations that most measures demonstrated to be beneficial in severe burns are likely useful in SJS/TEN.

#### Value of tests

- We found no evidence.

#### Drug reintroduction

- We found insufficient evidence.

# Polymorphic light eruption

Robert S. Dawe

Department of Dermatology, University of Dundee, Ninewells Hospital and Medical School, Dundee, UK

## Introduction

The condition polymorphic light eruption (PLE), also known as polymorphous light eruption, is one of the group of idiopathic photosensitivity disorders that also includes hydroa vacciniforme, chronic actinic dermatitis (photosensitivity dermatitis and actinic reticuloid syndrome), idiopathic solar urticaria, actinic prurigo, and juvenile springtime eruption. Although the cause of each of these conditions remains unknown, there are suggestions that the mechanism for some, including PLE, may be autoimmune. Here, I discuss some aspects of PLE (Figure 69.1), by far the commonest of these conditions, on which there is the largest volume of published literature. Where appropriate – for example, when discussing differential diagnosis – I mention other photodermatoses. Other photodermatoses, such as cutaneous porphyrias, DNA-repair disorders (such as xeroderma pigmentosa), and drug-induced photosensitivity, will be dealt with in future editions of the book and on the accompanying website.

## Background

### Definition

PLE is a recurrent abnormal reaction to sunlight – or artificial ultraviolet (UV) radiation – that occurs after a delay following exposure and heals without scarring [1–3].

### Prevalence

Questionnaire surveys have found that 10–21% of selected northern European and North American populations are affected [4–6]. PLE is diagnosed less frequently closer to the equator [7–9].

### Etiology

A commonly postulated mechanism is that PLE might be an autoimmune disorder in which there is an abnormal delayed hypersensitivity to an endogenous molecule rendered antigenic by UV exposure [10].

## Prognosis

Spontaneous resolution can occur, but is probably infrequent amongst those affected severely enough to be assessed in hospital [11].

## Diagnostic tests

The diagnosis is usually made on the basis of the clinical history. The following investigations are sometimes indicated:

- *Lupus serology*, when cutaneous lupus erythematosus is considered in the differential diagnosis; particularly if treatment with prophylactic phototherapy is being considered, antinuclear antibody and anti-Ro and La antibodies should be requested [12].
- *Histopathology*, when a superficial and deep, perivascular, dermal inflammatory infiltrate is seen. Histopathology and direct immunofluorescence can help differentiate PLE and lupus erythematosus [13,14].
- *Phototesting*. Monochromator phototesting is usually normal in PLE, but can be useful in excluding solar urticaria or chronic actinic dermatitis if these are considered possible alternative, or concomitant, diagnoses. Repeated irradiation provocation testing to 4 cm × 4 cm or larger areas is positive in a proportion of patients (<50% in some series), but can be helpful in cases of diagnostic uncertainty.
- *Patch testing and photopatch testing to sunscreens*. These are useful when sunscreen photoallergy or contact allergy is suspected as a coexistent diagnosis [15–18].
- *Porphyria plasma spectrofluorometry*. Cutaneous porphyrias occasionally feature as differential diagnoses, and can be excluded if this simple test is negative.
- *HLA class II typing* can help distinguish actinic prurigo (see later) [19,20].

## Aims of treatment

Treatments can be divided into prophylactic or suppressive. Prophylactic measures include sunlight avoidance and “desensitization” prophylactic phototherapy. Sunlight avoidance measures

Figure 69.1 A typical papular polymorphic light eruption.

include advice on behavior (for example, avoiding outdoor exposure between 10 a.m. and 3 p.m.), clothing (long sleeves and hat), topical broad-spectrum sunscreens, and environmental measures (such as applying UV-absorbing “museum film” to house and car windows for those severely sensitive to UV wavelengths). The aim of these measures is to reduce the frequency of and severity of the eruption.

The aim of prophylactic phototherapy is to increase the duration of sunlight exposure required to elicit PLE, and so improve the quality of life for those severely affected patients who cannot carry out normal activities (for example, putting out washing during daytime) because very limited sunlight exposure triggers the eruption. Suppressive treatment should alleviate symptoms (particularly itch), and speed the resolution of PLE when it occurs.

### Relevant outcomes

For prophylactic treatments, important outcomes are number of episodes of PLE (and their severity) and quality of life. For symptomatic suppressive therapies, the main outcomes are symptom severity (primarily itch) and the speed of resolution of the eruption.

### Methods of search

Studies were identified using the Medline (1966 to January 2006) and Embase (1988 to January 2006) databases, with search terms including “polymorphic/polymorphous light eruption AND (treatment OR prognosis).” Abstracts were read to determine which were likely to be relevant.

## Questions

### What is the prognosis for resolution of polymorphic light eruption for a severely affected patient living in a temperate country?

Follow-up of 94 Finnish patients (by questionnaire, supplemented by repeat clinical assessments of a subgroup) up to a mean of 32 years after onset found that 24% (95% confidence interval [CI], 16–34%) experienced resolution of their PLE and that 51% (95% CI, 41–62%) had milder PLE [11]. A recent report suggested that those with negative provocation tests may be more likely to proceed to remission than those with positive provocation tests [21].

## Comments

We have very limited information on the prognosis of PLE, and this one well-conducted follow-up study [11] involved a selected group of patients – those assessed in a hospital department and willing to attend for review. Our experience in Dundee (based on another severely affected patient group) is that a substantial proportion of those with PLE severe enough to require repeated yearly prophylactic phototherapy do, after several years, experience resolution, or marked improvement, so that they can then stop attending for treatment [22]. We do not know whether this is spontaneous resolution or whether it is a result of repeated phototherapy courses.

### Implications for practice

We can advise patients that spontaneous resolution is possible, but cannot reliably indicate how likely it is to occur. We still do not know whether repeated yearly courses of prophylactic phototherapy influence the long-term prognosis.

### Which form of prophylactic phototherapy – psoralen-ultraviolet A photochemotherapy or ultraviolet B monotherapy – should be prescribed for severely affected patients?

#### Efficacy

A randomized, patient-masked, controlled trial [23] including 25 adults found that narrowband (TL-01) ultraviolet B (UVB) was as effective as psoralen-ultraviolet A (PUVA) in preventing episodes of PLE following a treatment course, and that it was possibly more effective in reducing posttreatment subjective PLE severity scores. PUVA is more effective than broadband UVB [24].

#### Drawbacks

Both TL-01 UVB and PUVA produced PLE during the treatment course in about half of those treated [23]. High cumulative PUVA exposures administered to psoriasis patients increase the risk of later development of skin cancers, particularly squamous cell carcinomas [25]. Although the risks with UVB have not been well defined, it is probable that high cumulative UVB exposure will also result in some increased skin cancer risk (but less than with PUVA).

## Comments

The analysis of each of these studies comparing PUVA with UVB (narrowband and broadband) as prophylactic therapies for PLE took into account natural UV exposure measured with polysulfone badges after the treatment courses. Even with randomization (methods for which were not defined in either paper), differences in subsequent sunlight seeking or avoidance behavior in the groups compared could have influenced the results. Insufficient raw data were presented to allow retrospective calculations of the power of either study. Nevertheless, it can be safely concluded that PUVA is not much more effective than TL-01 UVB, and may even be less effective.

### Implications for practice

TL-01 UVB is the prophylactic phototherapy of choice for patients severely affected by PLE. When it fails to provide useful benefit, or when repeated episodes of PLE are provoked during therapy, PUVA can be considered.

## What are the effects of corticosteroids for mildly affected patients who develop polymorphic light eruption while on holiday?

### Efficacy

A randomized controlled trial of prednisolone 25 mg/day in a presumably mildly affected group (only 10 of 21 patients needed to take the study drug while on vacation) showed that it had an effect. PLE resolved more quickly (by a mean of 3.6 days; 95% CI, 0.6–6.1 days) with prednisolone than with placebo, despite the fact that for this study the patients were encouraged to continue sun exposure after they developed PLE [26].

It is unclear whether moderately potent or potent topical steroids help to suppress established PLE, but potent topical steroids may be of value prophylactically if applied immediately after exposure [27].

### Drawbacks

One of 10 patients who took a short course of oral prednisolone for PLE experienced “mild gastrointestinal disturbance and slight depression of mood” [26].

### Comments

For most patients with mild PLE, it is doubtful whether the small improvement produced by systemic prednisolone is sufficient to outweigh concerns about side effects. We do not know whether a potent topical steroid is of benefit for established PLE, but as systemic steroids have an effect it is possible that, at least for some patients, this may be beneficial.

### Implications for practice

Corticosteroids can have a small to modest effect on established PLE. While there is a lack of evidence that topical steroids have a similar effect, it may be appropriate to prescribe a potent topical steroid to use if PLE develops for patients whose problem is mild and confined to episodes induced by holiday sunlight. For some who are infrequently affected, application of a potent topical steroid each day before exposure may prove a useful approach.

## Can human leukocyte antigen class II typing distinguish polymorphic light eruption from actinic prurigo?

Actinic prurigo is strongly associated with HLA-DR4, and particularly HLA-DRB1\*0407 in the UK [19,20] and Mexico [28].

### Comments

PLE is distinguished from actinic prurigo on the basis of history and clinical features. The finding of a strong human leukocyte antigen (HLA) association with actinic prurigo, but not PLE, strengthened the evidence that these are distinct diseases. A study to determine the value of HLA class II typing as a diagnostic test in cases of clinical uncertainty about the diagnosis has not been performed, but such testing could be helpful.

### Implications for practice

In cases in which the diagnosis is in doubt, a negative HLA-DR4 test makes actinic prurigo less likely than PLE, while a positive HLA-DR4 is of limited value, as this antigen is common (about 25%) in most populations. A positive HLA-DRB1\*0407 test (rare in most populations) may help to rule in a diagnosis of actinic

prurigo (and exclude PLE), whereas a negative test result (found in almost 40% of UK cases of actinic prurigo) is of limited value.

### Key points

- PLE can improve over the years. This improvement may be spontaneous or partly due to repeated prophylactic phototherapy.
- Narrowband UVB and PUVA are similarly effective in preventing episodes of PLE.
- Oral prednisolone has a small or modest beneficial effect in PLE.
- Is not clear whether topical corticosteroids are of help in suppression of established PLE.
- HLA typing may occasionally be helpful in classifying a photodermatosis with features of both PLE and actinic prurigo.

# Infantile hemangiomas

Hossain Shahidullah

Derby Hospitals NHS Foundation Trust, Derby, UK

## Background

### Definition

Infantile hemangiomas (IHs) are benign endothelial tumors that characteristically have an initial rapid proliferative phase and a later, slower involutional phase (Figure 70.1). An IH may be composed of a superficial component with a bright red color and a blue-tinged color signifying the deeper component. They may be cutaneous or extracutaneous, although extracutaneous IHs will not be discussed in this chapter.

### Incidence/prevalence

The estimated incidence in children is 1.1–5% at birth [1–3], rising to 10% at 1 year of age [4,5]. The true incidence is not known, as they are often not present at birth, and the few prospective studies that have been conducted have methodological flaws. They were undertaken prior to the accurate classification of vascular birthmarks. IHs are three times more common in females and less common in some ethnic groups [6,7]. They are more common in premature infants and those with low birth weight; the incidence has been reported to be as high as 20% in premature infants with a birth weight of less than 1000 g [8,9].

### Etiology

The pathogenesis has yet to be fully elucidated, but clues are evident from a better understanding of vascular biology. Hemangiomas are proliferative lesions composed of endothelial cells (ECs), supporting pericytes, myeloid cells, and other cells, such as fibroblasts and mast cells [10,11]. Examination of isolated hemangioma ECs and whole tumors suggests that hemangiomas arise from uncontrolled clonal expansion of ECs [12]. The processes leading to the development of new blood vessels is complex and poorly understood. In proliferating hemangiomas, there is increased expression of vascular endothelial growth factor (VEGF) and basic fibroblast growth

factor [13,14]. Other growth factors, such as insulin growth factor and integrins relevant to angiogenesis,  $\alpha 5\beta 3$  and  $\alpha 5\beta 1$ , are expressed in the proliferative phase of hemangiomas [11,15]. In involuting hemangiomas, VEGF expression is reduced with a concomitant rise in the expression of apoptosis-associated proteins [16].

It is now apparent that ECs from IHs can be distinguished from other vascular tumors and malformations by surface markers such as GLUT-1, an erythrocyte-type glucose transporter protein, Lewis Y antigen, Fc gamma receptor II, and merosin [17,18]. These markers are also expressed at high levels on placental vasculature, leading workers to postulate hemangiomas may be a result of embolization of placental endothelial cells. Placental embolization has been shown not to be the case by using highly sensitive molecular genetic techniques which showed no evidence of maternal-fetal chimerism [19,20]. More recent work has focused on hypoxia as the underlying stimulus to development as a result of investigating the mechanism of action of propranolol in IHs (see later).

### Prognosis

The natural progression of hemangiomas can be divided into a rapid proliferative phase and a much slower involution phase (an artificial division, but clinically useful). The mean period of proliferation is 5 months (International Society for the Study of Vascular Anomalies data 2006), with an estimated 80% of growth of superficial IH achieved by 3 months [21]. Deeper lesions often proliferate up to 12 months of age. Involution may begin in the first year and may occur in one part, whilst other parts are still proliferating. The plaques often break up into smaller islands, and involution can continue for up to 10 years. The seminal studies of the natural history of untreated IH, from which much of current-day prognosis is based, showed that involution is completed in 50% by 5 years, 70% by 7 years, and 90% by 9 years [22,23]. There is a wide variation in what remains after involution, ranging from complete disappearance, telangiectasia, or more commonly a fibro-fatty residuum.

**Figure 70.1** In this 4-month-old child, a red mark was first noted on the right cheek at the age of 3 days. The mark grew rapidly during the first few months, despite early laser treatment. The mixed superficial and deep hemangioma involved the infraorbital area and ulcerated at the age of 3 months. As it was growing rapidly close to the eye and was likely to leave residual deformity, it was treated with a course of oral prednisolone, with stabilization of growth. Ophthalmic assessments were normal. The ulceration healed with wound care. At the age of 4 years, there was a residual fibroadipose structure, which was surgically corrected.

Sites such as the lips, nose, and cheeks leave cosmetically more disfiguring residua. IHs with ulceration tend to leave white or yellow scars.

### Treatment

There has been a major Cochrane review of interventions for infantile hemangiomas, and readers are directed to this very useful resource [24]. A significant but very important minority of hemangiomas may cause functional problems or even permanent cosmetic disfigurement. The decision to treat is obvious when IHs are potentially life threatening, or function threatening, as in those hemangiomas with heart failure, ocular compromise, or respiratory distress.

The site and size of the hemangioma will dictate the need for treatment. Sites such as the lips, nose, or ears are more likely to lead to permanent anatomical distortion and scarring [25,26]. The scarring from large plaque-like segmental hemangiomas on the face is potentially more serious than a similar lesion on the trunk.

The point in evolution of the hemangioma will also be relevant to management, and is closely linked with the age of the child. Hemangiomas of similar appearance may be in involution in an older child whilst in the growth phase in a child at 4 months old. The decision to treat surgically, for example, should normally be taken after the hemangioma has completed its growth phase.

The developmental stage of the child must also be taken into account, as children start becoming body aware at 2–3 years of age, but realization of a problem leading to stigmatization rarely occurs before 4–5 years of age. The decision to continue a wait-and-see approach must be balanced against the emotional consequences of this decision [27]. All children must be treated on an individual basis, but the parents should have information to help guide their decision. The information may take the form of serial photographs, examples of previous cases with before and after photographs, and a full discussion of the risks and benefits of any treatment modality. The following summarizes the indications for treatment

- life-threatening IHs (e.g., airway obstruction);
  - function threatening (such as visual or hearing compromise);
  - complications (e.g., ulceration);
  - large/segmental IHs likely to result in poor cosmetic outcome.
- The aims of treatment are resolution of the hemangioma without scarring, to reduce psychosocial morbidity, and prevent complications.

### Relevant outcomes

- Objective measures of resolution, such as redness, surface area, height.
- Residual skin changes, such as skin hypopigmentation, atrophy, fibro-fatty tissue, and telangiectasia.

### Methods of research

The Cochrane Library, Medline, and Pubmed until September 2012 were searched for terms including hemangiomas, propranolol, corticosteroids, and treatment. Abstracts were read and all potentially relevant studies were obtained in hard copy.

## Question

### Should propranolol be considered as first-line treatment for all problematic hemangiomas?

In a previous edition of this book it was reported that oral corticosteroids were effective in several case series, although no randomized controlled trials (RCTs) were available. It would be difficult to justify an RCT with a control observation arm in children with a complicated IH. Oral corticosteroids have until now been the gold standard for treatment of complicated IH. Since the first report of the unexpected discovery of the therapeutic benefit of propranolol used to treat heart failure in an infant with a facial hemangioma in 2008 [28], the vascular anomaly literature has mushroomed with reports of experience mainly in case series [29] (see Figure 70.2). However, as with any novel therapy (albeit an “old” drug), there should be a solid evidence base before it becomes accepted as the first-line therapy. This author is aware from experience that many physicians are already using it as first line because of its dramatic response.

Propranolol works by different mechanisms, including vasoconstriction, inhibition of angiogenesis, and induction of apoptosis [30]. Furthermore, it is believed that propranolol specifically induces regression of hemangioma endothelial cells through hypoxia-inducible factor-1 $\alpha$  (HIF)-mediated inhibition of the VEGF-A angiogenic axis [31].

The only published RCT of propranolol in IH compared propranolol 2 mg/kg per day with placebo for 6 months [32]. Forty children aged between 9 weeks and 5 years with facial IHs that were

**Figure 70.2** (a) Prior to treatment of upper eyelid hemangioma; (b) 5 months posttreatment with propranolol 2 mg/kg per day.

likely to result in cosmetic disfigurement or impair function were split into the two arms. The outcome measures were hemispheric volume, redness, and elevation scores, with serial photography as assessed by blinded observers. Some of the patients had not previously responded to oral corticosteroids. The results were analyzed on an intention-to-treat basis. Significant reductions in all parameters were seen from 1 month onwards. The IHs were clinically softer and less tense, although the dramatic change in the first 4 weeks had plateaued by 6 months. Furthermore, there were no reported serious side effects of bradycardia, hypotension, or hypoglycemia. The most common reported adverse effects were bronchiolitis, upper respiratory tract infection, and sleep disturbance.

### Drawbacks

This is data from small numbers of children, and the sample of patients used was quite mixed in age with very few early in their evolution and others who were quite advanced in their involution. The measurements were blinded, but volume measurements are notoriously prone to error. More objective measures are required, although in clinical practice serial photographs remain the most common method of assessment.

### Comment

There are many unanswered questions that need to be addressed with long-term prospective RCTs. The following shows the trials ([www.clinicaltrials.gov](http://www.clinicaltrials.gov) and <http://anzctr.org.au/TrialSearch.aspx>) being undertaken to resolve these issues:

- Does the use of propranolol bring forward the natural end point of evolution?
- Are there any long-term side effects?
  - **NCT01211080** Uncontrolled prospective observational study looking at cardiopulmonary and metabolic side effects of propranolol 2 mg/kg per day at 8 months.
- What is the best dose regime and for how long should it be given?
  - **NCT01056341** RCT of oral propranolol (1 or 3 mg/kg per day for 3 or 6 months) versus placebo in proliferating hemangiomas requiring systemic treatment.

- Should the extension of indications include noncomplicated IHs including small lesions?

- **NCT00744185** RCT of oral propranolol (3 mg/kg per day increasing to 4 mg/kg per day) for 30 days versus placebo in capillary hemangiomas. This trial is for IHs that would not normally be considered for treatment. Unfortunately, this study was terminated owing to recruitment difficulties.
- **NCT01512173** Double-blind placebo RCT comparing propranolol gel for 12 weeks with placebo.

- How should patients be selected for treatment?
- Is it better for those IHs in the expansion phase or should it be used at all stages of their natural history?

A case series showed that, in 37 patients in whom it was documented regression had ceased or greater than the age of 12 months, there was proven efficacy by comparing digital photographs [33]. The authors of this study stated that propranolol should be considered as first line for post-proliferative IH. The efficacy in the only completed RCT noted above was not 100%. Published case series report efficacy between 97 and 100%, although this is not always excellent/complete response [34–38]. This range is important in clinical practice because not all children with IH will respond to propranolol. The nonresponder rates can be up to 3% [34–38]. There need to be options for these patients.

- Is propranolol more effective than prednisolone?

As oral corticosteroids have been the previous first-line treatment, this modality should not be forgotten. A retrospective study comparing propranolol 2 mg/kg/day (for 8 months) with prednisone 4 mg/kg/day (5 months) showed that propranolol was more effective, cost effective and resulted in fewer surgical interventions and adverse effects [39].

- **NCT00967226** RCT of oral propranolol (2 mg/kg per day) versus oral prednisolone (2 mg/kg per day) for 4–6 months in symptomatic hemangiomas. This trial is ongoing.
- **NCT01072045** RCT of oral propranolol (2 mg/kg per day) versus oral prednisolone (2 mg/kg per day) for 60 days in proliferative or involuting hemangiomas.

There is marked variation in the pretreatment assessment of children, with protocols varying from inpatient assessment with pulse,

blood pressure (BP), echocardiogram, electrocardiogram (ECG) and blood glucose, to an outpatient setting with an ECG, BP, and glucose. The situation is constantly evolving as more experience is gained and monitoring is less stringent. When propranolol treatment for IHs is discussed with cardiologists, they are surprised by the level of assessment in patients with such low doses of propranolol compared with the doses used in heart failure and other cardiac diagnoses.

There are trials which are ongoing looking at other similar agents; for example, atenolol, nadolol, and timolol gel 0.5%. The latter is being studied very closely as it may bypass the need for pretreatment assessment and be easier for routine clinical use.

- NCT01010308 Nonrandomized intervention trial of nadolol 0.5–2 mg/kg per day for 6 months in 10 infants to explore the efficacy and safety of nadolol in IH.
- ACTRN12610001069044 RCT of topical timolol maleate gel 0.5%, one drop, versus emollient eye-drop placebo applied twice daily for 24 weeks (<http://anzctr.org.au/TrialSearch.aspx>).
- NCT01147601 RCT of topical 0.5% timolol for 6 months versus placebo, two or three drops to cover small (less than 3 cm) hemangiomas, twice daily.

The answer to the original question is that propranolol should be considered as first-line treatment for complicated IHs (except in patients with syndromic hemangiomas, such as posterior fossa malformations, hemangiomas, arterial anomalies, cardiac defects and coarctation of the aorta, eye abnormalities, and sternal abnormalities or ventral developmental defects (PHACES) syndrome [40], where there is potentially risk of cerebral hypoperfusion), but with several caveats. The dearth of long-term prospective data makes it impossible to say whether propranolol is better than other treatments in the long term, and larger multicenter studies are required. The safety profile is promising, especially compared with oral corticosteroids, but data collection should be continued over a longer period. The use of propranolol cannot be advocated in small asymptomatic lesions without more RCT evidence.

### Key points: infantile hemangiomas

- IHs are common vascular tumors with clinical heterogeneity and generally do not require intervention.
- For the small but significant complicated IHs that require intervention, steroids were considered first-line therapy. It has now been superseded by oral propranolol. There are two ongoing RCTs comparing oral prednisolone with propranolol.
- Propranolol is effective in the treatment of IHs, although there is only one small published prospective RCT demonstrating efficacy.
- There are numerous RCTs underway to confirm the efficacy, dose regime for oral propranolol and other trials of topical beta blockers.
- No long-term safety data are available, and there is a lack of evidence that the natural history of long-term involution is altered by propranolol treatment.
- There is no agreed screening or treatment protocol for the use of propranolol in IH.

## Background

Pruritus is defined as an unpleasant sensation that leads to a desire to scratch. It is the predominant symptom of skin diseases. All human beings experience this sensation in the course of their lifetime; therefore, it is important to make a distinction between acute itch, which is of a limited period of time ranging from seconds to <6 weeks, and chronic pruritus, which lasts for a period of >6 weeks [1]. The focus of this chapter is chronic pruritus. The consequences of pruritus range from trivial discomfort to excruciating distress. Chronic pruritus may cause substantial impairment of the quality of life and sleep of patients, which is similar to chronic pain [2–4].

Occasionally, heavy excoriations caused by intense pruritus can lead to serious secondary skin infection. Most skin diseases itch, especially if they have an inflammatory or epidermal component, and these diseases are discussed in the relevant chapters elsewhere in this book.

## Definitions

With a view to facilitating investigation and treatment, pruritus has been classified [5,6] into four categories, which are not mutually exclusive:

- pruritoceptive – itch generated in the skin due to skin disease;
- neuropathic – due to lesion(s) in the central or peripheral nervous system;
- neurogenic – caused by presumed circulating pruritogens, without evident disease of the nervous system;
- psychogenic – including delusional and affective disorder.

According to the International Forum on the Study of Itch (IFSI), pruritus has been classified into categories [1] that first distinguishes three clinical groups of patients as follows:

- Group I – pruritus on diseased (inflamed) skin;
- Group II – pruritus on nondiseased (noninflamed) skin;
- Group III – pruritus presenting with severe chronic secondary scratch lesions.

The first group includes underlying dermatological diseases, while the second and third groups include patients with systemic diseases, neuropathic itch, and psychiatric disorders, as well as diseases of pregnancy and drug-induced pruritus. The IFSI classification also contains an etiological classification of chronic pruritus: I, dermatological; II, systemic; III, neurological; IV, psychogenic/psychosomatic; V, mixed; and VI, other (undetermined origin) [1]. This new classification considers that some patients have more than one cause accounting for pruritus (category “mixed”) while in others no underlying disease can be identified (category “others”) [7].

Measurement of pruritus remains a challenge. In recent years, tools to assess its intensity using a visual analogue scale were validated [7,8]. Pruritus is subjective and, therefore, difficult to quantify, resort usually being made to a digital visual analogue scale [7,9]. Pruritus has also been measured indirectly by quantification of scratching or rubbing – for example, by using limb movement meters. However, the specificity of this method in distinguishing between restlessness and pruritus is unclear.

In summary, several instruments for the assessment of itch exist. However, it is clear that the use of a single measure does not insure an adequate and comprehensive assessment of itch [8,10].

## Incidence and prevalence

While it is often stated that pruritus is the most frequent symptom in dermatology and that it may also occur in other diseases (e.g., systemic, neurological), there are only a few studies about the prevalence and incidence of pruritus. In particular, chronic itch in the community has to be distinguished from chronic itch in specific populations, such as children and elderly people, and chronic itch in specific diseases [11]. One of the first population-based studies of pruritus was the so-called “Lambeth study” [12]. The point prevalence of pruritus and similar diseases such as prurigo and similar conditions was 8.2% in an urban adult population [12]. A population-based French study reported a 2-year prevalence of

14.4%, but there was no definition given of how chronic pruritus was defined [13]. A population-based study in Oslo, Norway, in 2000–2001 assessed among many other variables self-reported skin complaints. It was found that 8.4% of the survey individuals ( $n = 18747$ ) aged 30–76 had suffered from acute pruritus during the past 2 weeks [14]. In a study among employees attending an early skin cancer detection program, the point prevalence of chronic pruritus (>6 weeks) was 16.7% [15]. The Heidelberg pruritus prevalence study aimed at assessing the prevalence of pruritus (>6 weeks) in two urban populations and one world population. A previously validated questionnaire developed for the assessment of the prevalence and characteristics of chronic pruritus in the general population was used [16]. The point prevalence was estimated to be 13.5%, the 12-month prevalence 16.4%, and the lifetime prevalence 22% [16]. Women were affected more often than men, but a significant gender difference was only found for lifetime prevalence. Individuals with a non-German background reported significantly more chronic pruritus than Germans [16].

The findings of studies, especially in epidemiology, on pruritus are often difficult to compare or interpret owing to the fact that the parameters are not operationalized in a consistent manner and are not clearly defined. Besides, the symptom of “pruritus” often receives only minor attention in nondermatological specialties and is, therefore, often not considered in clinical studies. Pruritus is said to occur frequently in systemic diseases, but there is no epidemiological data on the frequency of pruritus in systemic diseases in general, and data for specific systemic diseases refer mainly to uremic pruritus [11]. Considering the most common skin diseases, pruritus is a defining feature of atopic eczema and daily pruritus is described in 84–91% of patients with atopic eczema [17,18]. According to a patient survey, atopic eczema patients were more likely to experience current pruritus and report a higher pruritus intensity compared with psoriasis patients [19]. Sixty-eight percent of chronic idiopathic urticaria patients were found to suffer from chronic pruritus which occurred daily [20].

### Prognosis

If a cause can be identified and dealt with (e.g., identifying the underlying dermatosis, relief of biliary tract obstruction in pruritus of cholestasis), the itch should remit. However, even when a cause has been identified (e.g., pruritus of chronic renal failure (CRF)), the itch may persist unabated despite best efforts. However, owing to increased research efforts, the number of therapeutic treatments has increased [21].

### Diagnosis

A careful history and examination are crucial. The quality, diurnal or nocturnal periodicity, and duration are very important. Itch with burning sensation and limited localization could be a form of neuropathic itch. A simple question, such as whether pruritus occurs in other family members, can indicate the possibility of scabies and avoid unnecessary investigation. A positive review of symptoms such as night sweats, loss of weight, and tremor may point to a systemic cause. Itching often occurs in brief bouts (e.g., at bedtime), and this information allows appropriate fine-tuning of treatment. Questionnaires such as the Eppendorf itch questionnaire [6] have proven useful in evaluating the intensity of itch and the resulting handicap, but there is no single and definite questionnaire fulfilling all needs [3,8,18]. As there is no definite itch questionnaire, it is obvious that additional tools are needed to better assess the different dimensions of chronic pruritus and better tailor management [8].

Examination for scabies burrows and for symptomatic dermographism (firm stroking of skin causes wheal, flare, and itch) should be done routinely. Care should be taken not to confuse induced secondary eczematous changes – as a consequence of rubbing or scratching due to a systemic cause of itch – with a pruritoceptive itch caused by a primary skin disease.

### Aims of treatment

The aim of treatment is to alleviate the itching, the distress it causes to the patient, and the secondary changes wrought in the skin by scratching. The European guideline on chronic itch has been published [21], and this addresses all medical disciplines that work with patients suffering from chronic itch.

### Relevant outcomes

In practice, total abolition of itching in the chronically pruritic patient is rarely achieved, and its partial amelioration is a more or less acceptable compromise outcome. For example, it is often possible to relieve itching to the extent that it does not interfere significantly with the patient's daily activities or cause excessive sleep disturbance at night.

### Methods of search

The following key words were used in a literature search: itch, pruritus, prurigo, scratch, excoriation.

We reviewed Pubmed, Medline, Embase, and the Cochrane Library and conference proceedings on pruritus. In addition, a manual search of the major German dermatology journals was carried out.

## Pruritus of chronic renal failure

### Definition

Pruritus of CRF is multifactorial in causation and variable in its clinical presentation, and therefore eludes precise definition. It is often unremitting, sometimes episodic. In the majority of patients it is generalized and symmetric in distribution, but could be localized – often to the shunt arm in dialysis patients. It is frequently associated with secondary skin complications, such as prurigo nodules and lichenified plaques.

### Incidence

The incidence of pruritus in CRF patients on dialysis has fallen in recent years from 70% 25 years ago to an estimated prevalence range between 22 and 60% [22–25]. In the largest epidemiological study to date, the international Dialysis Outcomes and Practice Patterns Study (DOPPS) determined that the prevalence of moderate to severe pruritus among more than 18 000 dialysis patients was 42%. No association was found between the presence of pruritus and gender, age, ethnicity, level of education, duration of end-stage renal disease, nature of underlying renal disease, or type of hemodialysis. Acute renal failure does not cause itching. It is extremely rare in children. It is more common in patients receiving hemodialysis than in those receiving continuous ambulatory peritoneal dialysis [26]. In patients on dialysis, it is an independent risk factor for mortality [25].

### Etiology

The cause of pruritus in CRF is unknown. It is thought to be a multifactorial disorder. Possible mechanisms include peripheral

C fiber neuropathy/abnormal innervation, mu opioid-kappa opioid imbalance, immune system derangement with a predominant TH1 proinflammatory response, and skin barrier abnormalities [27–30].

Recent studies, including the large DOPPS study, have demonstrated that higher serum calcium (albumin corrected) as well as phosphorus and calcium phosphorus product above  $>80 \text{ mg}^2/\text{dL}^2$  are all associated with itch intensity [24].

Xerosis is very common in CRF patients and probably contributes to itching in some patients, but it is not the major cause of itch [31].

## Prognosis

There are no systematic studies of the natural history of pruritus of CRF, but it is widely perceived to be unremitting and poorly responsive to treatment.

## Treatment aims

The primary object of treatment is to remove or mitigate any identifiable cause and abolish or at least ameliorate the itching. Patients with pruritus of CRF are frequently depressed and despairing of any effective remedy, so any treatment strategy needs to take depression into account, including counseling and the use of antidepressants. The only reliably effective treatment for pruritus of CRF is a kidney transplant.

## Outcomes

Reduction or abolition of pruritus should lead to resolution of the secondary manifestations of itching, including excoriation, eczematization, and secondary infection and relief of xerosis. Successful treatment should be reflected in an improvement in the patient's sense of well-being and quality of life.

## What are the guiding principles in choosing treatments for pruritus of chronic renal failure?

### General measures

Treatment of xerosis by emollients brings about some symptomatic relief. A double-blind trial using glycerol cream and paraffin showed a 75% reduction in pruritus and improvement in xerosis [32]. Another emollient containing gamma linoleic acid, an essential fatty acid, reduced itch significantly in a randomized, double-blind study of 22 patients [33].

A topical emollient containing palmitoylethanolamide (PEA), an endogenous fatty acid amide and a cannabinoid agonist, completely eliminated CRF pruritus in 38% of patients in an open-label 3-week trial [34]. Owing to the lack of controls and a significant placebo effect, further double-blind studies are warranted to examine the utility of PEA-containing emollients in the treatment of CRF pruritus.

Other topicals include topical anesthetics. In a double-blind study, pramoxine, a topical analgesic, relieved chronic kidney disease (CKD) pruritus in hemodialysis (HD) patients. It has no reported systemic side effects and is available as an over-the-counter agent [35].

In a crossover double-blind study, 19 out of 22 HD patients with moderate to severe pruritus treated with topical capsaicin 0.025% reported some relief and seven patients had a complete remission [36].

Topical tacrolimus 0.03%, a topical calcineurin inhibitor, reduced CRF pruritus in a case series and an open-label study [37]. However,

a randomized double-blind vehicle-controlled trial in 22 HD patients with moderate to severe pruritus revealed that the vehicle was similarly effective [38]. A recent study using pimecrolimus, a topical immunomodulating drug, similar to tacrolimus, was not effective either [39].

Secondary infection and eczematization can usually be controlled by topical treatment with a combination of antibiotics and corticosteroids. The intensity of pruritus correlates with skin temperature, so a cool environment, tepid showering, and wearing of light, loose-fitting clothes are beneficial.

### Systemic therapies

Although no results are available from controlled studies, oral antihistamines are of little or no value in the management of pruritus of renal failure.

Opioid  $\mu$ -receptor antagonists, which have been found to be effective in pruritus of cholestasis (see later), have also been advocated in the treatment of pruritus of renal failure. However, the published results have been conflicting. A randomized, placebo-controlled crossover study by Peer *et al.* [40] showed that the oral  $\mu$ -receptor antagonist naltrexone (50 mg/day) was effective, with all of 15 patients responding with reduced itching. However, a subsequent placebo-controlled double-blind crossover study that included 23 patients taking oral naltrexone 50 mg daily, with a visual analogue scale and a detailed score to measure pruritus intensity, showed no difference in comparison with placebo [41]. Nalfurafine hydrochloride is a kappa opioid agonist that mitigates the effect of mu opioids. In two large, randomized double-blind placebo-controlled multicenter studies it reduced itch significantly in comparison with placebo.

Nalfurafine hydrochloride has a good safety profile and is well tolerated. Its major adverse effect is insomnia. This drug is currently only available in Japan for HD patients with CKD pruritus [42,43].

Gabapentin, a gamma-aminobutyric acid analogue anticonvulsant, was found effective for uremic pruritus in a double-blind controlled study [44]. The investigators showed that 24/25 patients responded to 300 mg administered after dialysis three times a week. Manenti *et al.* made similar observations with a lower dose of 100 mg on a similar dosing schedule [45]. Pregabalin is another amino acid derivative of gamma-aminobutyric acid that is similar to gabapentin. It has better bioavailability and requires a lower dose. However, there are as yet no controlled studies on its use for uremic pruritus. Therefore, gabapentin remains the most effective treatment for CKD itch.

### Phototherapy

The efficacy of broadband ultraviolet B (UVB) phototherapy in pruritus of renal failure was first suggested by Gilchrist *et al.* in a large open study [46]. Since generalized pruritus abated even though only half of the body was treated, a systemic effect was inferred. A subsequent meta-analysis of the results of randomized controlled trials (RCTs) came to the conclusion that broadband UVB is the treatment of choice for moderate or severe uremic pruritus [47].

Narrowband UVB is less erythemogenic, and was reported in a small pilot study to reduce CKD pruritus [48].

### Other treatments

Other treatments that have been successfully used in anecdotal reports for CKD pruritus include thalidomide and butorphanol, a kappa opioid and  $\mu$ -antagonist [49,50].

### Drawback of current therapies

Opioid  $\mu$ -receptor antagonists carry a risk of hepatotoxicity, and they inactivate opioid pain killers that are being given concurrently. Kappa opioids cause insomnia.

Gabapentin is excreted by the kidney, and high doses may induce adverse neurotoxic effects such as somnolence, dizziness, and coma. Thus, patients should be started on a low dose (100 mg) and monitored closely.

### Implications for clinical practice

The causes of pruritus in CRF are obscure, so it is unsurprising that there are no highly effective treatments. Despite best efforts, treatment is often at best only moderately successful.

The current mainstay of therapy for pruritus of CRF includes emollients, topical anesthetics, low-dose oral gabapentin or UV phototherapy three times a week. Kappa opioids may be helpful for CRF pruritus.

#### Key points: pruritus of chronic renal failure

- Pruritus of CRF is a chronic debilitating disease that mostly affects patients on HD.
- The cause of the itch is probably multifactorial, and generally poorly responsive to treatment.
- Topical regimens include emollients and topical anesthetics, such as pramoxine and capsaicin, but these agents are difficult to employ over very large area.
- Broadband UV radiation, low-dose gabapentin, pregabalin, and kappa opioid agonists are effective treatments.

## Pruritus of cholestasis and hepatic disease

### Definition

This itch – often intense and unbearable in cholestasis – is frequently widespread; but unlike generalized pruritus due to other causes, symmetrical involvement of the palms of the hands and soles of the feet is common and typical [51]. When due to cholestasis, it is often, but not invariably, accompanied by jaundice. Patients usually rub rather than scratch, and secondary excoriation, eczematization, and skin infection are therefore less common than in pruritus of CRF.

### Incidence

Itching occurs in 20–25% of patients with cholestasis [52] and is severe and invariable in cholestasis due to primary biliary cirrhosis (PBC) [53]. It seems that the prevalence of itch in PBC is much higher than in other liver diseases [54].

### Etiology

Recognized causes of pruritus include PBC, primary sclerosing cholangitis, obstructive choledocholithiasis, carcinoma of the bile duct or head of the pancreas, and viral hepatitis. Less common

causes include cirrhosis. Cholestasis and associated itch can also be drug-induced [55]. The cause of the itching, originally thought to be due to bile acids, is now also believed to be due to increase in activity of lysophospholipase autotaxin and its product lysophosphatidic acid [56].

Other pruritogens involved in cholestatic itch are opioid peptides synthesized in the liver and acting on  $\mu$ -opioid receptors located mainly in the central nervous system [57].

### Prognosis

Relief of biliary obstruction by surgery or a stent causes rapid abatement of pruritus. In patients with itch due to parenchymal liver disease (e.g., such as hepatitis C infection, PBD), itching is variable and persistent, with a capricious response to treatment.

### Diagnosis

The combination of jaundice and generalized pruritus, with the skin being otherwise essentially normal, is highly suggestive of a cholestatic cause for the itch. However, cholestatic itching can occur without jaundice, as in pregnancy cholestasis. In such cases, the presence of elevated plasma bilirubin and alkaline phosphatase and bile acids in plasma and urine strengthens the diagnosis.

### Treatment aims

When an obstructive cause can be identified and relieved, treatment of the itch is symptomatic and short term. In patients in whom the pruritus is secondary to intrahepatic cholestasis, hepatitis, or cirrhosis, the aim is to alleviate or, if possible, abolish the itching.

### Outcomes

Amelioration or abolition of itching.

### What are the guiding principles in choosing treatment for pruritus of cholestasis or liver disease?

#### General measures

These include a cool environment, tepid showers, and wearing light, loose-fitting clothes.

Frequent application of a lotion of calamine with 1% menthol is also well appreciated by most patients.

#### Efficacy

Any extrahepatic obstruction of the biliary tract should be relieved, and will be followed by rapid remission of the pruritus. Intrahepatic cholestasis is more challenging to treat. In many patients, the frequency and intensity of cholestatic pruritus does not correlate with the severity of bile obstruction. Moreover, in many cholestatic patients, administration of bile acid resins does not improve itch. Oral antihistamines are generally ineffective. In selected cases in which pruritus is intractable and severe, liver transplantation should be considered.

Oral cholestyramine (4g administered before and after breakfast) is hallowed by tradition but not by controlled clinical trials [58]. Since it works by binding intestinal bile acids and other anions, thereby decreasing enterohepatic circulation, it is ineffective in the presence of total biliary obstruction.

Oral ursodeoxycholic acid 8–10g/day, a naturally occurring hydrophilic bile salt, was found to be effective in pruritus of PBC in only two of 11 trials reported in a meta-analysis of RCTs [59]. However, a recent meta-analysis of nine published trials for

intrahepatic cholestasis of pregnancy (ICP) showed that it is more effective than cholestyramine [60]. Also, in a head-to-head comparison it was shown to be more effective than cholestyramine [61].

Rifampicin, which induces cytochrome P-450 enzymes in the liver, thereby reducing putative liver-derived pruritogens, was found to be effective in the treatment of cholestatic pruritus at a dosage of 350–600 mg/day [62,63]. Recent meta-analysis of randomized trials revealed that rifampin is a safe and effective short-term treatment for cholestatic pruritus [64,65].

The oral opioid antagonists nalmefene (5–20 mg twice daily) and naltrexone (50 mg/day) were shown to be effective in reducing pruritus in two controlled studies, which both used a visual analogue scale and a scratching activity monitoring system to quantify itch [66,67]. A reduction in itch by 50–90% was seen in these studies. Naloxone, a parenterally administered opioid antagonist – infused at 0.2 µg/(kg min) – was also found to be effective in a double-blind, randomized, placebo-controlled trial [68].

Kappa opioid agonists that have less side effects, such as nalfurafine, have been proposed to be effective antipruritics for cholestatic pruritus [69]. Butorphanol inhaler, a kappa agonist and mu antagonist available in Europe and the USA, was reported to alleviate intractable itch of hepatitis C [50].

Selective serotonin antidepressants have been reported to be of some effect for cholestatic pruritus. In a double-randomized study, sertraline in doses of 75–100 mg has shown to be effective for cholestatic pruritus [70]. Paroxetine in dose of 20 mg has been reported to be effective for cholestatic itch [71].

Gabapentin, which is an effective therapy for different types of chronic itch, has not shown any efficacy for cholestatic pruritus in a double-blind placebo-controlled study [72].

Other treatment modalities advocated to include odansetron (8 mg daily orally in one RCT) [73].

Extracorporeal elimination of pruritogens has been used with different techniques, including plasma separation and the Molecular Adsorbent Recirculating System (MARS®; albumin liver dialysis), and reported in more than 20 patients to be effective for cholestatic itch [74,75].

Phototherapy with UVB has recently been reported to have reduced cholestatic itch by more than 60% in more than 70% of cholestatic pruritus patients with different types. The mean number of irradiations required to obtain this effect was  $26 \pm 17$  (average duration of phototherapy: 8 weeks) [76]. Other treatment modalities include an open study of bright-light therapy directed into the eyes up to 60 min twice daily [77].

### Drawbacks

Cholestyramine, although probably mildly effective, is unsatisfactory owing to poor patient compliance (due to the taste and constipation). Rifampicin and the opioid µ-receptor antagonists, although of proven effectiveness, are associated with a high frequency of liver toxicity. The latter also cause opioid withdrawal symptoms, which can be largely prevented by starting with a low dose and increasing gradually [78].

### Comments

Ursodeoxycholic acid seems to be the first-line therapy for cholestatic pruritus but has limited efficacy.

Rifampicin and opioid antagonists are effective in the treatment of cholestatic itch, but the incidence of adverse effects is high with rifampicin and opioid antagonists, and they should be used cautiously [79].

### Implications for clinical practice

Patients receiving active treatment for cholestatic pruritus with rifampicin or opioid antagonists should be regularly and frequently monitored for adverse effects, especially in the liver.

### Key points: pruritus of cholestasis and hepatic disease

- Where there is an identifiable obstruction, its removal will result in rapid relief of pruritus.
- Rifampicin and opioid antagonists are of proven value as second-line measures, but they should be used cautiously, owing to the frequency of adverse side effects.

## Pruritus in hematological diseases

### Definition

Itching is a frequently presenting symptom of Hodgkin's and non-Hodgkin lymphomas, cutaneous T-cell lymphomas (see also Chapter 34 on cutaneous T-cell lymphoma), polycythemia vera (PV), and occasionally also occurs in other hematological disorders, including myelodysplasia and lymphoblastic leukemia. Pruritus associated with hematological diseases is characteristically triggered by contact with water. Pruritus, often localized, also occurs in association with iron deficiency.

### Incidence

In Hodgkin's lymphoma, the incidence of itch occurs in 30% of patients [80]. More recent data obtained in a retrospective study at M.D. Anderson showed the incidence of itch in Hodgkin's lymphoma patients was 19% [81]. In PV, itching ranges between 31 and 48% of the patients [82,83]. Figures from an epidemiological study in Finland involving a survey of over 40 000 adults showed that 13.6% of iron-deficient men complained of frequent pruritus, contrasting with 5.3% in men who were not iron deficient ( $P < 0.001$ ) [84]. The corresponding figures for adult women were 7.4% and 5.1% ( $P < 0.01$ ).

### Etiology

The underlying pathophysiology of lymphoma and hematological-associated pruritus is poorly understood. Pruritus in PV is significantly associated with a low mean corpuscular volume and raised leukocyte count [82]. Other proposed pathogenetic factors include elevated plasma histamine levels and elevated tissue fibrinolytic activity [85]. The pathogenesis of itching in iron deficiency is unknown.

### Prognosis

Treatment of PV often improves the pruritus, but in 20% of patients the itch is persistent [86]. Symptomatic treatment also greatly improves the quality of life for affected patients. The benefits conferred by iron supplements in patients with pruritus associated with iron deficiency are unclear, since no controlled trials have been done.

## Diagnosis

Any patient complaining of pruritus triggered by contact with water at any temperature, and without a rash, should be suspected of having PV or myelodysplastic syndrome and hematological malignancies. The diagnosis of lymphoma is confirmed by lymph node biopsy or organ biopsy. The diagnosis is confirmed by demonstrating raised hemoglobin, hematocrit, red cell mass, platelet count, and leukocytosis. Iron deficiency is established by demonstrating a lowered serum iron and high total iron-binding capacity.

## Treatment aims

Itch in lymphoma and itch in PV are distressing symptoms, and the aim should be to achieve its abolition or at least reduction to tolerable levels. Iron deficiency should be corrected in order to ameliorate itching.

## Outcomes

Reduction or abolition of itching.

## What treatments are available for pruritus of polycythemia vera?

### General measures

Pruritus in PV, sometimes water-induced ("bath-time itch"), is distressing and disabling. Because there is often no visible accompanying eruption, the sufferer receives scant sympathy. Explaining this to family members and caregivers forms an important part of the management of these patients.

### Efficacy

Although blood histamine levels are often elevated,  $H_1$  antihistamines are rarely effective.

Selective serotonin reuptake inhibitors (SSRIs), paroxetine 20 mg/day and fluoxetine 10 mg/day, were shown to effectively reduce itch in eight out of 10 patients in an open-label trial [87].

Aspirin has anecdotally been found effective in some patients with PV [88]. Narrowband UVB administered three times weekly (10 patients) and photochemotherapy with 8-methoxypsoralen-ultraviolet A (PUVA) two or three times weekly, with 15 treatments (in 11 patients) have been claimed to be effective in open studies of PV [89,90].

Interferon alfa ( $IFN-\alpha$ ) is an effective drug for PV, and has been noted to be effective in the control of PV-associated pruritus [88,91].

A Janus kinase inhibitor 2 ( $JAK1/2$ ) has been recently tested in a phase II study involving advanced PV and essential thrombocytosis patients. All patients with pruritus reported a rapid and sustained reduction of this symptom [92].

A phase I study using a selective  $JAK2$  inhibitor (TG101348) reported a significant reduction in constitutional symptoms, including pruritus [93].

An inhibitor of the mammalian target of rapamycin that was administered to a cohort of nine patients with aquagenic pruritus with primary myelofibrosis and post-PV myelofibrosis resulted in complete resolution of itch in all patients [223]. The exact mechanism by which these agents produce a reduction in the pruritus is currently unknown.

The efficacy of oral iron supplements in patients with pruritus and iron deficiency has not been established in clinical trials.

### Drawbacks

PUVA and narrowband UVB are usually well tolerated, but relapse occurs within weeks of the end of treatment.

## Comments

Although the published evidence is weak, it is likely that phototherapy or photochemotherapy is effective in ameliorating pruritus in some patients with PV. The new  $JAK$  inhibitors seem promising for treatment of PV itch. The value of iron supplements in the treatment of pruritus associated with iron deficiency is questionable.

## Implications for clinical practice

Phototherapy and photochemotherapy offer safe and often effective, although temporary, relief of pruritus in PV.

### Key points: pruritus in polycythemia vera and patients with iron deficiency

- Pruritus in PV, often triggered by contact with water, can be effectively relieved in some patients using either narrowband UVB or PUVA.
- Low-dose SSRIs are effective therapy for PV and myelofibrosis pruritus.
- The  $JAK$  inhibitors seem to have antipruritic effects, but further controlled trials are needed to explain their role in pruritus treatment.

## Pruritus of endocrine diseases

### Definition

#### Thyroid disorders

Generalized pruritus is seen commonly in patients with hyperthyroidism, particularly in cases of thyrotoxicosis of Graves' disease [94]. Hypothyroidism is less frequently associated with itch, and is associated with skin xerosis [95].

#### Diabetes

Generalized itching does not appear to occur at increased frequency in diabetic patients [94]. However, pruritus due to other disorders in diabetic patients, including dermatophyte infections, xerosis, diabetic neuropathy, or *Candida* infections (such as may be seen in the anogenital region), may occur [94]. In particular, diabetic neuropathy may account for localized itch without rash. A recent large study from Japan reported truncal itching in 11% of patients with type 2 diabetes. Patients with abnormal sensation were at risk for this type of itch [96].

Pruritus in diabetics is commonly noted in the anogenital area in association with candida intertrigo. It may be more widespread if diabetes is complicated by CRF in perforating collagenosis, such as in Kyrle's disease. In contrast, pruritus in hyperthyroidism is usually widespread, and may be a severe presenting symptom.

### Incidence/prevalence

Most textbooks cite diabetes as an important cause of chronic generalized pruritus. This belief dates from 1927, when a study of the skin in 500 patients with diabetes reported an incidence of pruritus of 6.5%, with about half of the cases being generalized; however, there was no control group [97]. A more recent study of 300 diabetic and 100 matched nondiabetic patients reported that pruritus vulvae was more common in the diabetic group (18.4% vs 5.6% in controls), but the frequency of generalized pruritus did not differ between the two groups [98].

Although itching is a widely recognized symptom of overactive and underactive thyroid disease, figures for the incidence and prevalence are scarce. A recent study in 120 hyperthyroid patients reported pruritus, often generalized, in 60% [94].

In hypothyroidism, the incidence of pruritus is unknown, but it seems rare.

### Etiology

Pruritus in diabetes is commonly localized, it is frequently noted in the anogenital area due to candidiasis, and is directly related to poor diabetes control [98]. Occasionally, it can be due to diabetic neuropathy, xerosis, or CRF. The cause of itching in thyrotoxicosis is unknown.

### Prognosis

The prognosis of pruritus in diabetes depends on the effectiveness of control of underlying hyperglycemia. Correction of thyroid dysfunction leads to remission of the itch in thyrotoxicosis.

### Treatment aims

The achievable aim should be complete abolition of localized pruritus in diabetics, and of generalized pruritus in thyrotoxicosis. The itching in hypothyroidism can be reduced, but complete relief is often difficult to attain.

### Outcomes

Freedom from itching in diabetics and patients with thyrotoxicosis.

### How can localized itch of diabetics be effectively treated? How should the patient with generalized itching due to hypothyroidism or hyperthyroidism be managed?

#### General measures

Anogenital pruritus in diabetics is helped by careful drying after bathing, use of loose-fitting underwear, and, most importantly, adequate control of diabetes (also see section on “Anogenital pruritus”). Mitigation of generalized pruritus of thyrotoxicosis can be achieved by measures to cool the warm, moist itchy skin. These include wearing light clothing, tepid showering, a cool ambient temperature, and calamine lotion.

#### Efficacy

There are no clinical trials of treatment of diabetic pruritus. For the anogenital itch, since the majority are due to candidiasis, anti-*Candida* treatment using topical imidazole antifungals is usually effective if combined with adequate management of the diabetes. Oral anti-*Candida* agents may also be required. Pruritus in hyperthyroidism should be treated by correction of thyroid function.

#### Drawbacks

Since diabetics are strongly predisposed to mucocutaneous candidiasis, the relapse rate of anogenital candidosis and its associated pruritus is high even if the diabetes is controlled.

#### Comments

Oral antihistamines are ineffective in relieving of pruritus due to endocrine disease. Topical antihistamines and local anesthetics should be avoided in anogenital pruritus in diabetics, owing to risk

of sensitization. Topical corticosteroids should be used cautiously and for a limited time.

### Implications for clinical practice

Sustained remission of anogenital pruritus of diabetes mellitus can be difficult to achieve, especially in women with vulvo-vaginal candidosis. Reservoirs of reinfection, such as *Candida* paronychia, also need to be vigorously treated (also see section on “Anogenital pruritus”).

#### Key points: pruritus in thyroid disease and diabetes mellitus

- In diabetes, pruritus is usually localized and could be associated with diabetic neuropathy.
- Anogenital itch is common in diabetics and is frequently due to candidiasis.
- In hyperthyroidism, pruritus is generalized and multifactorial.
- Treatment of diabetic anogenital pruritus includes adequate control of diabetes, combined with local or occasionally systemic anti-*Candida* therapy.
- Apart from general measures, the treatment of pruritus of thyrotoxicosis consists of correcting the thyroid dysfunction.

## Anogenital pruritus

### Definition

This is defined as chronic localized intense pruritus affecting the perianal area (pruritus ani), scrotum (scrotal pruritus), and the vulva (pruritus vulvae). Although frequently idiopathic, anogenital pruritus may be a manifestation of dermatosis or systemic or neuropathic disease. If persistent, it leads to secondary skin lesions (e.g., lichenification locally), and it also causes severe distress and sleep disturbance.

### Incidence/prevalence

Pruritus ani occurs in 1–5% of the adult population, and males are more commonly affected than females [99]. Precise figures for the incidence and prevalence of pruritus vulvae are unavailable. It can occur at any age, but in its chronic presentation it is common post-menopausally [100].

In 20 patients suffering from anogenital pruritus without any skin diseases or anorectal pathology, lumbo-sacral radiculopathy and degenerative changes in the lower spine were confirmed in 80% of cases [101].

Itching was the single most frequent presenting symptom occurring in 70% of patients consulting a clinic for vulvar disease [102].

Out of 93 women with psoriasis, 44.1% experience vulvar discomfort, including 19.4% with itch, 10.8% with burning, and 14% with both itching and burning sensations. Psoriatic lesions were present on the vulva in 23.7% of subjects. There were no significant correlations between burning/itching intensity and global psoriasis severity [103]. Vulvar itching was significantly more common in diabetic women (18.4%) than in controls. Itching in the genital and perianal area is significantly more common in diabetic women and is significantly associated with poor diabetes control [98].

## Etiology

Common dermatoses that involve the anogenital area and cause pruritus include psoriasis, atopic dermatitis, lichen sclerosus, lichen planus, scabies, pediculosis, allergic contact dermatitis (especially with perfumed soaps; 18 of 40 patients with pruritus ani had positive patch tests) [104], and seborrheic dermatitis (also see Chapter 25). Dermatitis medicamentosa due to contact allergic sensitization to long-continued topical application of antipruritics, especially local anesthetics and antihistamines, is common [105]. Local problems causing pruritus include threadworms, warts, hemorrhoids, lichen simplex chronicus, carcinoma, and urinary or fecal incontinence. In women, vaginitis – especially vaginal candidiasis – is an important local cause, and estrogen deficiency is an important systemic cause. In one study of 1104 patients with pruritus vulvae, 946 (85%) had candidal or trichomonal vaginitis [106]. Diabetes mellitus is a common systemic cause in both sexes. Vulvar dermatitis (frequently leading to pruritus vulvae) is frequently associated with atopic diathesis [107].

A prospective study in 42 women with pruritus vulvae and 42 asymptomatic controls did not provide evidence to support the routine determination of iron status in patients presenting with pruritus vulvae [108]. Psychogenic factors (“stress”) are often cited in cases in which none of the above causes are found, but stress is probably a frequent cause or a co-factor.

## Prognosis

Anogenital pruritus is characteristically chronic and poorly responsive to treatment, even when a cause has been identified and treated. The itch–scratch cycle is especially hard to break at this site.

## Diagnostic tests

Examination of the skin and mucous membranes, including the genito-anal region, is necessary. Skin biopsy for diagnosis of a dermatosis may be required. Depending on the clinical findings, appropriate tests to identify bacteria, fungi, or candida should be performed. Anal or anogenital pruritus requires stool investigations (e.g., parasites, giardia lamblia, worm eggs), as well as proctoscopy, rectoscopy, and perhaps colonoscopy, depending on the findings. Gynecological examination is required in genital pruritus. In case of suspected contact dermatitis, a careful history of topicals used is essential, and patch testing may be necessary. In 50 women with vulvar pruritus, 52% had at least one positive patch-test reaction to allergens such as cosmetics, preservatives, and topical medications [109]. If a neurological etiology is suspected (especially in chronic back pain patients), magnet resonance tomography of the spine (especially lumbo-sacral spine) is necessary to rule out stenosis of the intervertebral foramen or protrusion of the discs. In severe cases of chronic anal, genital, or anogenital itch without any underlying etiology or no improvement by therapy or counseling, a psychiatrist may be necessary.

## Treatment aims

Treatment should be targeted at breaking the itch–scratch cycle. Breaking the cycle allows restoration of effective stratum corneum barrier function.

## Outcomes

Effective treatment should lead to gradual lessening of the compulsive desire to rub or scratch, with accompanying resolution of lichenification, pigmentation, and excoriation. Sleep disturbance should diminish. Restoration of an effective barrier function

enables the anogenital skin to resist normal “wear and tear” as well as minor irritancy.

## What are the roles of local and systemic treatments in the management of anogenital pruritus?

### General measures

Overenthusiastic cleansing and use of irritant toiletries, perfumed soaps, foam baths, or sensitizing topical medicaments should be discontinued. The anogenital area should be washed regularly with plain water and air dried or gently dabbed with cotton wool. For pruritus vulvae, wiping should always be from front to back. In severe cases of anogenital pruritus, sitz baths (warm plain water hip baths) bring about rapid relief. Ointments are preferable to creams, owing to the presence of potentially irritant preservatives in the latter. Silicone barrier and zinc oxide ointments help retain moisture in affected skin, thereby enhancing healing.

### Efficacy

When anogenital pruritus is a manifestation of a primary skin disease or local lesion such as hemorrhoids, threadworms, or vaginitis, apart from general measures, the management is that of the causative dermatosis or local pathology. Adequate control of underlying diabetes mellitus is essential, together with treatment of the invariable underlying candidosis. In postmenopausal pruritus vulvae, systemic hormone replacement therapy should be considered.

Vaginal candidosis is also an important cause of pruritus vulvae in nondiabetic women. In one study, 17 of 38 women (45%) with pruritus vulvae were found to have *Candida albicans* infection [110]. Although underlying local or systemic disease can be identified in many patients, the cause in some patients with pruritus vulvae is elusive (idiopathic vulval pruritus). Most of these patients receive topical steroid treatment. There are no controlled trials, but one open study of 65 patients showed that 56 of these reported complete relief in 2 days following topical fluocinolone acetonide [111]. Intralesional injection of triamcinolone has been proposed for recalcitrant pruritus vulvae. Of 45 patients, 35 experienced relief for at least 1 month (mean 5.8 months) following a single injection [112]. For exceptionally resistant and handicapped patients, multiple local intradermal injections of ethanol have been reported to be effective by several authors. In one double-blind study [113], 14 of 17 patients reported complete relief by undermining the skin of the vulva, the vaginal mucosa, and perianal skin [114,115]. Of 16 women, 15 experienced immediate relief of itching and no relapse occurred after follow-up periods ranging from 3 months to 3 years.

Topical corticosteroids are the standard treatment for perianal pruritus if it persists despite the removal or treatment of the underlying causes, or when no cause can be found. Controlled trials are lacking, but in a recent study in idiopathic perianal pruritus one group of 28 patients applied topical methylprednisolone cream twice daily for 2 weeks, with a second group of 32 patients using a liquid cleanser only [116]. The results were similar in the two groups, with over 90% of patients responding ( $P > 0.05$ ). Intralesional triamcinolone has also been used for recalcitrant pruritus ani. Nineteen patients with idiopathic pruritus ani were treated with triamcinolone hexacetonide intralesionally for 4 weeks (dosage 5–20 mg weekly) [117]. Very good improvement occurred in 14 patients and fair improvement in two. No skin atrophy was noted. Fifteen patients with anogenital pruritus were treated with paravertebral injections at the level of L5–S1 (2.5 mL triamcinolone

acetone 10 mg/mL, 2.5 mL lidocaine 1% divided into five or six separate injections). The degree of pruritus was significantly reduced 2–4 weeks after the injections [101].

Topical capsaicin is a recognized treatment for various types of localized pruritus. A recent double-blind placebo-controlled crossover study compared capsaicin 0.006% cream with 1% menthol cream in idiopathic intractable pruritus ani [118]. Use of the capsaicin cream three times daily for a month led to partial relief of pruritus in 31 of 44 patients, and the menthol cream was invariably ineffective. Intralesional 5% phenol has also been used with success in patients with idiopathic pruritus ani resistant to conventional modalities. In an open study of 67 patients, 62 (92.5%) experienced complete relief [119]. Five of them subsequently relapsed, but sustained remission followed after a repeat injection.

According to a systematic review, limited evidence supports the efficacy of clobetasol propionate, mometasone furoate, and pimecrolimus in treating genital lichen sclerosis [120]. Clobetasol propionate 0.05% cream and pimecrolimus 0.1% cream were both effective in relieving pruritus and burning pain. There were no significant differences between the two substances [121].

### Drawbacks

Potent topical corticosteroids are widely prescribed for most types of anogenital pruritus, often for long periods of time. Although usually effective, they may mask underlying primary pathology, including neoplasia, infection, and allergic contact sensitization. Local steroid atrophy may also occur. Similar caveats apply to intralesional triamcinolone injections. Although safe, patient compliance with topical capsaicin is poor owing to its burning action. Experience with intralesional injection of ethanol or phenol is too limited to warrant consideration except in the most intractable cases.

### Comments

Careful history-taking, clinical examination, and investigation of patients with pruritus vulvae or ani will frequently be rewarded by discovery of an underlying primary cause. Embarking on prolonged topical potent steroid application should be delayed until these avenues have been thoroughly explored.

### Implications for clinical practice

A patient presenting with pruritus ani or vulvae should also always undergo rectal and/or vaginal examination. Patients with a long history of poor response to topical medications should be considered to have dermatitis medicamentosa until proved otherwise by patch testing.

#### Key points: anogenital pruritus

- Anogenital pruritus is usually a symptom of underlying skin disease, local disease, systemic disease, or lumbo-sacral degenerative changes.
- Diabetes mellitus, candidosis, and rectal or vaginal malignancy should be sought and treated.
- Contact dermatitis is common, and patch testing should be carried out in treatment-resistant patients.
- General measures, especially avoidance of irritants and the use of skin-friendly anogenital hygiene, encourage restoration of the stratum corneum barrier.
- In idiopathic cases, topical corticosteroids may be helpful, but they may mask malignancy and other underlying disease.

## Drug-induced itch

### Definition

Drug-induced itch is defined as generalized itching without skin lesions, caused by a drug. Drug-induced itch can be acute (<6 weeks), most frequently caused by opioids and chloroquine [122]. It usually resolves after stopping the drug. Chronic itch (>6 weeks) usually does not spontaneously stop after withdrawal of the drug [122]. It is frequently caused by hydroxyethyl starch (HES).

### Incidence/prevalence

In the Boston Collaborative Drug Surveillance Program studies that were published in the *Journal of the American Medical Association*, drug-induced itch without a rash accounted for approximately 5% of adverse cutaneous reaction in prospectively followed hospitalized patients. Adverse cutaneous reactions occurred in 3% of the patients [123,124], except for itch induced by HES. The latter is described as occurring in 12.6–44% of patients treated with HES [125–127]. Opioid-induced itch is a common problem after epidural and intrathecal administration of opioids, usually localized on the face, neck, and upper thorax. No reliable data are available on the incidence and prevalence rates. The variation in the incidence has been reported to range from 50 to 90% [128,129].

There are no epidemiological data on how frequently drugs cause itch in a population of itch patients.

### Etiology

Many drugs must be used with caution in human immunodeficiency virus (HIV) patients, who may be susceptible to hypersensitivity reactions, drug interactions, and idiosyncratic reactions. Some of them may present with pruritus without skin lesions. It has recently been shown that spinal opioid-induced itch is evoked independently of opioid-induced analgesia by signaling through an opioid receptor splice isoform expressed in itch-mediating spinal neurons [130].

A great number of drugs ranging from antihypertensive drugs to antiepileptic drugs need to be considered as a possible cause of pruritus [122].

Severe generalized or localized itching can be induced via the following mechanisms:

- cholestasis – for example, oral contraceptives or other estrogens, captopril, chlorpromazine, valproic acid, erythromycin, sulfonamide, minocycline;
- hepatotoxicity – oral contraceptives or other estrogens, testosterone and other anabolic steroids, phenothiazine, phenytoin, acetaminophen, isoniazid, halothane, sulfonamide, minocycline, cyclooxygenase-2 (COX-2) inhibitors (e.g., celecoxib);
- deposition – HES;
- xerosis cutis – retinoids, beta-blockers, tamoxifen, busulfan, clofibrate;
- phototoxicity – 8-methoxypsoralen, doxycycline;
- neurologic – tramadol, codeine, cocaine, morphine, fentanyl, topiramate;
- idiopathic – chloroquine, quinidine, clonidine, gold salts, lithium, angiotensin-converting enzyme inhibitors;
- new anticancer drugs (i.e., epidermal growth factor receptor inhibitors), as well as anti-melanoma drugs (i.e., ipilimumab).

## Prognosis

If the offending drug is discontinued, the itching resolves. There are no studies on the prognosis, except for HES-induced itch. The mean duration of HES-induced itching is 15 months, mainly depending on the amount of HES deposited. Tissue deposition of HES is dose dependent and time dependent [131]. Neural deposition of HES was confined to a total dose of HES exceeding 210 g. After administration of 414 g, 32% of the patients suffered from pruritus, in comparison with 1% after a dose of 150 g [125,132].

## Diagnostic tests

In HES-induced itch, a skin biopsy with immunoelectron microscopy may demonstrate HES deposits in the skin.

## Aims of treatment

The aim of treatment is to abolish or reduce itching.

## Relevant outcomes

- Abolition of drug-induced itch.
- Prevention of drug-induced itch.

## Are there any drugs more likely to induce pruritus? Are there any treatment options other than discontinuing the offending drug?

### Evidence summary: efficacy

There are no controlled trials investigating the mechanisms and treatment options for drug-induced itch, except for opioid-induced itch. The literature shows that cholestasis and hepatotoxicity appear to be the most frequently reported triggers of this type of pruritus.

In HES-induced itch, topical capsaicin therapy at concentrations ranging from 0.025 to 0.5% four to six times daily showed antipruritic potency in a case report [133] and case series [134]. Single patients were reported to respond to oral naltrexone 50 mg daily in HES-induced itch [135,136]. Two cases of intractable pruritus in drug-induced cholestasis were successfully treated by extracorporeal albumin dialysis using MARS [137].

According to a quantitative systematic review of randomized trials on the pharmacological control of opioid-induced pruritus, there is a lack of valid data on the efficacy of interventions for the treatment of established pruritus [138]. Naloxone 0.25 µg/(kg h) was found to be efficacious in relieving postoperative pruritus in children and adolescents in a double-blind, prospective, randomized controlled study [139]. Naloxone infusion rates >1 µg/(kg h) significantly reduced the incidence of opioid-induced itch in postoperative pediatric patients receiving morphine [140].

Celecoxib 200 mg failed to relieve pruritus in a prospective randomized placebo-controlled trial involving 60 women undergoing cesarean section [141].

Naloxone 2 µg/(kg h) intravenously (i.v.), naltrexone 6 mg orally, nalbuphine i.v. (the optimal dose remains to be determined), and droperidol 2.5 mg or 5 mg i.v. or epidurally are effective in preventing opioid-induced pruritus [138,139]. The optimal dose is one that provides adequate relief of pruritus without increasing pain scores. There was a lack of evidence for any antipruritic efficacy with prophylactic propofol, epidural and intrathecal epinephrine, epidural clonidine, epidural prednisone, intravenous ondansetron, and intramuscular hydroxyzine [138]. A case report suggests rifampicin 300 mg i.v. twice daily in pruritus after morphine treatment in a cancer patient [142].

## Key points: drug-induced itch

- Drug-induced pruritus has multiple mechanisms. The treatment of drug-induced pruritus centers on discontinuation of the triggering drug.
- To prevent opioid-induced itch, naloxone, naltrexone, nalbuphine, and droperidol are efficacious.
- According to case reports, topical capsaicin therapy and oral naltrexone may be used to treat HES-induced pruritus.

## Human immunodeficiency virus and itch

### Definition

HIV-related itch is defined as generalized or localized itching in patients with HIV infection or acquired immune deficiency syndrome (AIDS).

### Incidence/prevalence

Itching is a very common symptom in this population, but epidemiological data about the incidence and prevalence of itch in HIV and AIDS populations are scarce. A recent study in 897 American HIV-infected patients revealed a pruritus prevalence rate of 6% [143]. HIV viral loads higher than 55 000 copies/mL had a higher prevalence of pruritus [143]. A recent study from Spain revealed that 31% of HIV patients attending a skin health program reported pruritus [144]. When the prevalence of pruritus in 310 patients with chronic HIV and hepatitis B and C virus infection was prospectively determined, the prevalence rate was 28% in patients with hepatitis C and HIV and 25% in those with hepatitis B and HIV [145]. When 84 Ugandan pruritus patients were investigated, 19% were found to be HIV positive [4].

### Etiology

HIV/AIDS patients are prone to develop a number of pruritic dermatoses [38,146–148]. The most common causes of HIV itch are skin xerosis, papular pruritic eruptions and prurigo of HIV, seborrheic dermatitis and cutaneous infections as tinea, folliculitis, and insect bite reactions. Other causes include photosensitive and drug reactions [149].

Systemic causes of pruritus in HIV are relatively uncommon, but may occur in HIV nephropathy, hepatic failure due to hepatitis B or C, and systemic lymphoma [38,146,147].

Pruritic papules of HIV have been found to be highly associated with arthropod bites in one cross-sectional study [150].

Severe pruritus may lead to secondary scratch lesions; for example, such as lichenification and prurigo nodularis. Lichenification is often triggered by other pruritic dermatoses. Prurigo nodularis can be caused by HIV-related dermatoses or HIV-related systemic diseases, but may also occur without any known cause. Generalized asteatosis clinically presents as xerosis or dry skin, accompanied by pruritus. It increases with disease progression, and CD4 counts decline [146].

As many as half of AIDS patients may never have specific causative or categoric diagnoses identified. Some authors term this “idiopathic pruritus” [146]. In these cases, it is most likely that itching is directly related to the HIV infection – for example, HIV viral load, immune dysregulation, reduced Th1, increased Th2, increasing levels of immunoglobulin A and immunoglobulin E (IgE), and increased eosinophils [144,151].

## Prognosis

The prognosis depends on the prognosis of the HIV infection and on the stage of the AIDS disease, as well as on optimum antiviral therapy.

## Diagnostic tests

The tests performed depend on the relevant differential diagnoses concerning the etiology. They may include HIV viral load, CD4 count, IgE, eosinophils, bile acids, transaminases, alkaline phosphatase, creatinine, blood urea nitrogen, and radiographic and sonographic examinations.

## Aims of treatment

Abolition of itching, reducing ichthyosis, reducing discomfort, improving the quality of life.

## Relevant outcomes

Abolition of itch, improvement of the quality of life.

## Are there any treatment options for human immunodeficiency virus-induced itch? Is one therapy superior to the others in improving quality of life in human immunodeficiency virus-induced itch?

### Evidence summary: efficacy

In a controlled but nonrandomized study, treatment of pruritus in HIV-1 disease did not reveal any difference between indomethacin 25 mg t.i.d., pentoxifylline 400 mg t.i.d., hydroxyzine hydrochloride 25 mg t.i.d., and 0.025% triamcinolone lotion (120 mL/week) [152].

In a noncontrolled, nonrandomized study, UVB phototherapy produced significant relief of pruritus and improved the quality of life in HIV-positive patients suffering from primary pruritus ( $n = 7$ ) and pruritic eosinophilic folliculitis [153]. The safety of phototherapy in HIV-positive patients has been debated, but it is considered to be safe [154,155].

Thalidomide has been used to relieve HIV-related pruritus in the setting of prurigo nodularis. A randomized study in 10 HIV patients suffering from prurigo nodularis showed a greater than 50% response in reduction of itch over 3.4 months when thalidomide was taken for longer than 1 month (eight of the 10 patients). The dosage ranged from 33 to 200 mg daily. Three patients developed thalidomide peripheral neuropathy [148].

A case report describes the use of hypnosis in the treatment of generalized itching in three HIV-positive men [156].

### Key points: human immunodeficiency virus and itch

- Pruritus is an important cause of discomfort and morbidity in HIV and AIDS patients.
- Treatment of pruritus in HIV and AIDS depends on the underlying etiology. Patients need careful evaluation in order to determine the underlying cause. In these cases, causative treatment is possible (e.g., treatment of an underlying systemic cause, treatment of underlying specific dermatoses, discontinuation of a drug).
- In pruritus that is not related to a specific dermatological or systemic disease, optimal antiviral treatment is best.
- Very limited data suggesting that symptomatic relief can be achieved with UVB phototherapy and that thalidomide may be helpful for pruritus associated with HIV-related prurigo nodularis need confirmation.

## Psychogenic itch

### Definition

Psychogenic itch refers to pruritus associated with psychiatric diseases and psychological factors (e.g., the delusional state of parasitophobia or neurotic excoriations). It may be generalized or localized.

### Incidence/prevalence

There are no data on the incidence and prevalence of psychogenic itch. It is estimated that psychogenic excoriation occurs in 2% of dermatology clinic patients [157]. One study showed >70% of itch patients had a psychiatric comorbidity or psychosomatic cofactors [158]. Another study demonstrated 22% of itch patients to have a psychiatric disease [159]. The occurrence of itching of the face was significantly more common in psychogenic itch [159]. Itching occurred in 32–42% of hospitalized psychiatric patients. When itching dermatoses and systemic causes were excluded [160,161], itching was experienced by 17.5% of psychiatric inpatient during a depressive episode [162]. It disappeared in all depressive patients with co-occurring itch during treatment with antidepressants [162].

### Etiology

Depression, anxiety, and schizophrenia have been described as causes of psychogenic itch. Neurotic excoriations and the delusional state of parasitophobia can be accompanied by psychogenic itch. Neurotic excoriations are characterized by excessive scratching and picking of normal skin, but this is not necessarily associated with pruritus. One study revealed that 58% of patients with psychogenic excoriations had a current major depressive syndrome and that 45% of patients with psychogenic excoriations had obsessive-compulsive disorder [163].

### Prognosis

There are no data on the prognosis of psychogenic itch. It is most likely that the prognosis depends on the underlying psychiatric disease and its treatment.

### Diagnostic tests

Psychiatric consultation and counseling for diagnosis or verification of the underlying psychiatric disease are necessary. Diagnostic criteria from the French Psychodermatology Group were proposed and validated [164,165]. Three compulsory criteria (localized or generalized itch without primary skin lesions, duration >6 weeks, no somatic cause) and optional criteria (three out of seven required) should be present; for example, a chronological relationship with one or several life events, variations in intensity associated with stress, predominance during rest or inaction, improvement by psychotropic drugs [164].

### Aims of treatment

Abolition of itching, reducing discomfort, improving the quality of life.

### Relevant outcomes

Abolition of itch and improving the quality of life.

## Which treatment options are efficacious for psychogenic itch?

### Evidence summary: efficacy

There are no controlled trials investigating the treatment of psychogenic itch. SSRIs, such as paroxetine 20 or 30 mg daily or fluoxetine 20 mg daily, showed efficacy in case reports [166,167]. In elderly patients, cardiac side effects may occur, so these drugs should therefore be applied with caution.

Mirtazapine, a nonadrenergic and specific serotonergic antidepressant, was associated with significant relief in a case of chronic neurotic excoriations at a dosage of 15 mg/day [168]. Dry mouth, sedation, and weight gain are the most commonly reported side effects, but its advantages are once-daily dosing and its lack of addictive potential.

There are no controlled trials of behavioral or psychotherapeutic treatments for neurotic excoriations. In case reports, behavioral techniques such as “habit reversal” have been found to be effective [157].

Narrowband UVB showed improvement in 70% of patients with resistant psychogenic excoriations in a case series [169].

### Key points: psychogenic itch

- Treatment of psychogenic pruritus depends on the underlying etiology.
- Paroxetine and mirtazapine were found to be useful in case reports of psychogenic pruritus and neurotic excoriations.

## Itch and senescence

### Definition

Generalized or localized itching in patients over the age of 65 may be called senescent pruritus or elderly itching.

### Incidence/prevalence

A Turkish study investigating 4099 elderly patients found that pruritus ranked first in the distribution of skin diseases, with 11.5% complaining about pruritus. Women were more frequently affected (12.0%) than men (11.2%) [170]. With regard to the age group, patients aged over 85 had the highest prevalence rate (19.5%). With regard to seasonal variations, senescent pruritus was among the five most frequent diagnoses in all seasons and was most frequent in winter (12.8%) and fall (12.7%) [170]. Pruritic diseases were the most common in a study from Thailand (41%) that identified xerosis (which for the authors was identical with senescent pruritus) as being the most frequent condition (38.9%) in a total of 149 elderly patients [171].

One population-based study found a significant association between age and lifetime prevalence of chronic itch [172].

### Etiology

Aging skin is characterized by a decline in the regular functions of the skin (e.g., cell replacement capacity, barrier function, immune

responsiveness, sebum production, sweat production, sensory perception, and wound healing). Current theories of senescent pruritus range from xerosis cutis to degenerative changes in the peripheral nerve endings. One study detected increased histamine release and skin hypersensitivity to histamine in pruritus of the elderly [173].

### Prognosis

No data are available on the prognosis.

### Diagnostic tests

The elderly are more likely to take multiple medications that may cause itching (see also the earlier section on “Drug-induced itch”). As the elderly are also more likely to have systemic diseases that can potentially cause itching, a precise dermatological and general examination should exclude an underlying systemic disorder. Laboratory studies may include erythrocyte sedimentation rate, a complete blood cell count with differential leukocyte count, blood urea nitrogen, creatinine, liver transaminases, alkaline phosphatase, bilirubin, thyroid function test, serum iron, ferritin, and radiographic and sonographic examinations (also see reference [21]). The diagnosis of senescent pruritus is made on the basis of chronic pruritus after other causes of itching have been excluded.

### Aims of treatment

Abolition of itching, reducing discomfort, improving the quality of life.

### Relevant outcomes

Abolition of itch.

## What are the major causes of senescent pruritus? Are there any effective therapies for itch in the elderly?

### Evidence summary

Therapy depends on an underlying systemic disease, if present.

A double-blind placebo-controlled trial including 19 patients with senile pruritus who were treated with oxatamide 30 mg b.i.d. for 2 months showed complete suppression or marked improvement of pruritus in 79% of the patients [174].

A controlled nonrandomized study in 60 patients suffering from senescent pruritus and 20 control individuals (20 patients unaffected by pruritus in the elderly, aged 63–83, median age 77) was carried out and showed complete or marked improvement in 41% of patients treated with loratadine 10 mg and in 38% of patients treated with terfenadine 120 mg orally. There were no significant differences between the groups [173]. Exact results for the control group were not given in the study.

Ten patients with essential senescent pruritus were treated with ciclosporin A 5 mg/kg body weight per day for 8 weeks in an open uncontrolled study. Ciclosporin A treatment significantly reduced the itch intensity in all patients. In eight patients, pruritus ceased in the fourth week of treatment. No relapses occurred until 3 months after discontinuation, except for one patient suffering from mild localized pruritus [175].

From the clinical point of view, it is well known that the elderly frequently suffer from itching caused by xerosis cutis, asteatotic dermatitis, or stasis dermatitis. Topical emollients (also with urea or anesthetic agents) are usually very helpful, but there is a paucity of published quantitative evidence of their role.

**Key points: itch and senescence**

- Pruritus in the elderly is quite frequent, with a gradually increasing prevalence in increasing age.
- Therapy includes treatment of an underlying systemic disease, if present, and use of emollients, especially in xerosis cutis.
- Everyday experience suggests that xerosis cutis plays an important role.

**Neuropathic itch****Definition**

Neuropathic itch is defined as pruritus that is caused by a disease at any point along the peripheral or central pathway of the nervous system.

**Incidence/prevalence**

Itching is reported by up to 58% of patients suffering from herpes zoster and up to 30% of patients suffering of postherpetic neuralgia, mainly affecting the head, face, and neck [176,177]. There are no epidemiological data on, for example, notalgia paresthetica, brachioradial pruritus, or pruritus in multiple sclerosis.

**Etiology**

Notalgia paresthetica, brachioradial pruritus, postherpetic neuralgia/itch, pruritus in multiple sclerosis, trigeminal trophic syndrome (TTS), and itch post cerebral vascular accident (CVA) and in Jakob–Creutzfeldt demyelinating syndrome [178] are clinical forms of neuropathic itch.

Notalgia paresthetica is characterized as localized pruritus medial to the scapular area, frequently accompanied by a hyperpigmented patch. It is described as being caused by degenerative changes in the vertebrae corresponding to the dermatome of itching [179]. When 43 patients with notalgia paresthetica were evaluated, 61% had spinal changes judged to be relevant [180]. The striking correlation between the localization of notalgia paresthetica and spinal pathology suggests that spinal nerve entrapment may contribute to notalgia paresthetica [179,180]. A retrospective study with 65 patients suffering from notalgia paresthetica revealed 32.3% with stenosis and 47.7% with degenerations of the spinal column [181]. However, the significant reduction in intra-epidermal nerve fiber density suggests that damage to the peripheral nerves is a more important etiological factor than spinal changes in notalgia paresthetica [181].

Brachioradial pruritus is characterized by intense pruritus of the dorsal and lateral parts of the underarms and elbows, usually presenting with burning, prickling, or picking sensations. Application of ice packs provides relief; this sign is nearly pathognomic for this condition [182]. Brachioradial pruritus may be attributed to neuropathic conditions such as chronic cervical radiculopathy, cervical spondylosis, and transverse myelitis [7,183–185]. A study in 41 patients with brachioradial pruritus revealed cervical spine changes in all patients: 80.5% of these patients had stenosis of the intervertebral foramen or protrusions of the cervical discs leading to nerve compression [186]. The location of the nerve compression lesions correlated significantly with the dermatomal localization of pruritus: in 90.2% patients marked with C5 location, and in 100% with the C6 location on the dermatom chart [186]. A spinal cord tumor has been reported in a patient with brachioradial pruritus [187]. The occurrence of brachioradial pruritus in several members of one family affecting two generations has also been described [188].

The temporal course of itching in brachioradial pruritus in some patients and the histological changes in the skin, similar to those caused by UV light, indicate that sunlight may be a contributing factor [189]. According to a recent study in 95 patients, 80% had seasonal symptoms [190]. However, radiographic evaluation was only performed in 36 patients. The role of UV light and the histological changes in the skin, similar to those caused by UV light, need to be determined [190].

It is believed that cervical spine disease is the most relevant etiological factor in brachioradial pruritus [190].

In 20 patients suffering from anogenital pruritus without any skin disease or anorectal pathology, lumbosacral radiculopathy and degenerative changes of the lower spine were confirmed in 80% of cases [101].

Postherpetic itch after shingles affecting the head or neck is more likely to occur than after shingles of the torso [176]. Neuropathic itch is more likely to be caused by lesions of the peripheral rather than central neurons. One type of facial neuropathic itch that progresses to scratching-induced ulcers is TTS. Intractable pruritus and profound cutaneous deafferentation makes scratching painless in TTS. The most common brain lesion causing neuropathic itch is cerebral infarction, particularly strokes that affect the lateral medulla or the lateral pons [176]. Small-fiber polyneuropathy (SFPN) is characterized by chronic pruritus of both feet, the feet and legs, the hands and legs, and sometimes also spreading throughout the body. Pain, paresthesias or dysesthesias may be accompanied. Pruritus is fairly common in familial Jakob–Creutzfeldt disease, noted in 19% of patients [191]. Pruritus in multiple sclerosis appears to be rare, rather occurring in early disease stage, but epidemiological data are missing [192]. No epidemiological data are available on post-CVA itch.

**Prognosis**

The prognosis depends on identifying an underlying cause – such as cervical radiculopathy (brachioradial pruritus) and degenerative changes in the vertebrae (notalgia paresthetica) – and on the pathogenicity of the underlying disease (e.g., multiple sclerosis, cerebral infarction).

**Diagnostic tests**

Radiological examinations of the spine, including magnet resonance tomography, should be performed in cases of brachioradial pruritus and notalgia paresthetica as well as magnet resonance tomography of the brain in cases of multiple sclerosis or brain tumors [181,185,186,193]. Further neurological examinations are necessary according to the suspected etiology of pruritus; for example, in SFPN, distal-leg skin biopsy and autonomic function testing.

**Aims of treatment**

Abolition of itching, reducing discomfort, improving the quality of life.

**Relevant outcomes**

Abolition of itch.

**What are the major causes of neuropathic itch?****Are there any effective treatments for it?****Evidence summary: efficacy**

Topical local anesthetics (e.g., polidocanol) are of symptomatic help, but there are no RCTs in neuropathic pruritus.

Topical capsaicin 0.025% four times daily showed significant antipruritic efficacy in a randomized, double-blind, crossover, placebo-controlled 10-week study in 20 patients with notalgia paresthetica. Seventy percent of the patients treated with capsaicin and 30% of those treated with placebo improved [194]. In 24 patients with notalgia paresthetica, relief of up to 90% was achieved in 70% in a noncontrolled, nonrandomized study with topical capsaicin 0.025% four times daily [195].

When 15 patients with brachioradial pruritus were treated with capsaicin 0.025% four times daily for 3 weeks, 10 of 13 patients who completed the study experienced significant or complete relief after 3 weeks in comparison with an untreated arm that served as a control [196].

A systematic review of topical capsaicin in the treatment of pruritus identified two studies concerning treatment of brachioradial pruritus [188,194]. The study on notalgia paresthetica reported a significant difference in the first phase of a crossover study favoring capsaicin over placebo in a visual analogue scale for itch intensity, but failed to report data for a second outcome measure. The final study on brachioradial pruritus reported no significant reduction in itch between capsaicin and placebo [107].

When 16 patients with notalgia paresthetica or brachioradial pruritus were treated with cutaneous field stimulation once daily, 20–30 min a time for 5 weeks in an open trial, pruritus was reduced by 49% at the end of the fifth week in comparison with baseline values [197].

Gabapentin is an anticonvulsant structurally related to the neurotransmitter gamma-aminobutyric acid. The mechanism of action is unclear. Several case reports demonstrated efficacy of gabapentin for brachioradial pruritus. The dosage needed ranged from  $6 \times 100$  mg daily or  $3 \times 300$  mg daily up to  $3\text{--}6 \times 600$  mg daily [198–201]. RCTs are missing.

Oxcarbazepine, a keto-analogue of the anticonvulsant carbamazepine, decreased pruritus when administered to a group of five patients at a dosage of 300 mg twice daily [202].

Fifteen patients with neuropathic scrotal pruritus were treated with paravertebral injections consisting of 2.5 mL triamcinolone and 2.5 mL lidocaine 1% divided into five or six separate injections, with a significant decrease in the mean pruritus scores assessed by the patients before and after therapy [101].

In a retrospective case series, 16 patients with segmental pruritus were treated with deep intramuscular stimulation acupuncture to the paravertebral muscles in the dermatomal segments of the body affected. Twelve patients had complete resolution and four had partial resolution of the pruritus. Relapses occurred in 37% of patients within 1–12 months, requiring further acupuncture. The author described this form of pruritus as “neurogenic pruritus” [203]. Physical therapy including strengthening and stretching exercises have been reported as a reasonable first-line or adjunctive treatment in cases of notalgia paresthetica [204].

#### Key points: neuropathic itch

- Neuropathic itch is an important differential diagnosis in patients suffering from chronic itch.
- Neuropathic itch needs appropriate diagnostic evaluations and neurological assessments.
- Topical capsaicin treatment and systemic gabapentin therapy seem to be effective, but RCTs are missing.

## Pruritus in pregnancy unrelated to skin diseases

### Definition

Pruritus during pregnancy unrelated to skin diseases, especially unrelated to pregnancy-specific dermatoses and without skin lesions, can occur as ICP [205,206]. It may be associated with clinical jaundice. Particularly in the older literature, some authors used the terms “pruritus gravidarum” and “intrahepatic cholestasis of pregnancy.” ICP is the only specific dermatosis of pregnancy that starts solely with itch. Owing to scratching, skin lesions such as papules, nodules, excoriations, and crusts may result later. Some authors have suggested that pruritus gravidarum in women with an atopic predisposition can result in prurigo of pregnancy [207]. According to a newer classification of specific dermatoses of pregnancy, this resembles atopic eruption of pregnancy [205].

### Incidence/prevalence

Epidemiological studies focusing on the prevalence of pruritus during pregnancy unrelated to skin diseases are limited. Interestingly, pruritus is described as the main dermatological symptom during pregnancy and is observed in approximately 18% of pregnancies [208].

A French prospective study of 3192 pregnant women showed that 1.6% had pruritus [209]. Seventeen patients (0.5%) had pruritus gravidarum, while all of the other cases were pregnancy-specific dermatoses [209]. The prevalence of pruritus in pregnancy was reported to be 4.6% in an Indian study of 500 pregnant women, but with the exception of four cases of pruritus gravidarum all of them were suffering from specific dermatosis of pregnancy [210]. The prevalence of pruritus gravidarum was 0.8% [210]. The rate of intrahepatic cholestasis is higher in Chile, related to ethnic and dietary factors. A prevalence rate of 13.2% was found for pruritus gravidarum and 2.4% for cholestatic jaundice of pregnancy [211]. ICP was diagnosed in 3% of pregnant patients in a retrospective two-center study [205].

### Etiology

Pruritus in pregnancy can occur with or without intrahepatic cholestasis. Intrahepatic cholestasis is associated with dyslipidemia, which may contribute to the pathogenesis of intrahepatic cholestasis [212]. The elevation of low-density lipoprotein cholesterol and the reduction of high-density lipoprotein cholesterol may prove to be a useful marker for the early identification of intrahepatic cholestasis of pregnancy and differentiation from pruritus without intrahepatic cholestasis [212]. The cause of the itching in cholestasis, originally thought to be due to bile acids, is now also believed to be due to increase in activity of lysophospholipase autotaxin and its product lysophosphatidic acid [56], also see section on “Pruritus of cholestasis and hepatic disease.”

ICP represents a genetically linked, hormonally induced reversible cholestasis that typically manifests in late pregnancy [205]. Of patients with ICP, 88% reported previously affected pregnancies. ICP is associated with significant fetal risk (premature birth, intra-partal fetal distress, stillbirth), and small-for-date children may be seen [205].

It is estimated that pregnant women take three to eight different medications – some over-the-counter ones, some prescribed by physicians [213]. Drug-induced pruritus during pregnancy is not one of the more probable differential diagnoses, but chloroquine-induced pruritus in malaria therapy during pregnancy is a frequent

cause in tropical regions, with a prevalence of 65%. According to one study, it occurred in 75% of those affected within 24 h after consumption and was described as severe by over 60% of the patients [214].

### Prognosis

In ICP there is a possibility of recurrence during a subsequent pregnancy that can imply an increased risk to the fetus, such as impaired development, intrauterine death, or premature birth [205,210]. One population-based study compared pregnancies in women with and without pruritus gravidarum. Of 159 197 deliveries, 376 (0.2%) occurred in patients with pruritus gravidarum. Using a multivariate analysis, the following conditions were found to be significantly associated with pruritus gravidarum: twin pregnancies, fertility treatments, diabetes mellitus, and nulliparity. No significant differences were noted between the groups with regard to perinatal outcomes, such as birth weight, low Apgar scores, or perinatal mortality. Pruritus gravidarum, associated with multiple gestations, fertility treatments, diabetes mellitus, and nulliparity, is not associated with adverse perinatal outcomes. However, there are higher rates of labor induction and cesarean delivery [215].

### Diagnostic tests

Diagnostic tests include bile acids, transaminases, alkaline phosphatase, cholesterol, and lipids. Measurement of glutathione S-transferase  $\alpha$  (GSTA), a marker of hepatocellular integrity, provides a test of liver dysfunction that distinguishes between pruritus gravidarum with and without intrahepatic cholestasis [216]. Levels of autotaxin and lysophospholipase autotaxin may be utilized as markers of ICP [56].

### Aims of treatment

Abolition of itching, reducing discomfort, improving the quality of life.

### Relevant outcomes

Abolition of itch.

### What are the major causes of pruritus during pregnancy unrelated to skin diseases? Are there any effective treatments?

#### Evidence summary: efficacy

Aspirin showed significant antipruritic efficacy in a systematic review when it was administered at a dosage of 600 mg four times daily in comparison with chlorpheniramine 4 mg three times daily applied during late pregnancy. Aspirin was more effective in relieving itch, but chlorpheniramine was more effective than aspirin when a rash was present [217]. Aspirin may not be given during the last trimester, as it can lead to early occlusion of the ductus arteriosus.

There are no studies on the efficacy of antihistamines for the treatment of pruritus during pregnancy, but there are studies concerning their safety. The older sedating antihistamines, such as chlorpheniramine, dimetindene, diphenhydramine, and hydroxyzine, are considered relatively safe during pregnancy, on the basis of long-term experience and several independent animal studies, and these agents have not shown any teratogenic effects [213]. In animal studies during pregnancy, astemizole, terfenadine, and cetirizine did not show any notable effects in influencing the fetus, but terfenadine and fexofenadine led to decreased fetal weight gain. In younger generation antihistamines (e.g., levocetirizine), animal

studies so far have not demonstrated any impairment of pregnancy or of embryonic and fetal development. Second- and third-generation antihistamines should not be administered during the first trimester of pregnancy. If antihistamines are necessary during this period of pregnancy, the older sedating ones are preferable. Fexofenadine, terfenadine, and astemizole are not suitable for treatment during pregnancy [213].

There have been no studies investigating the efficacy of glucocorticosteroids in patients with pruritus during pregnancy.

Cholestyramine binds bile acids. According to uncontrolled studies, it may be effective in up to 70% of patients suffering from ICP [206,207]. Ursodesoxycholic acid enhances the excretion of bile acids. It is very effective when administered at daily doses of between 450 and 1200 mg, as shown in four small controlled trials [207]. Others recommend 15 mg/kg per day or 1 g, either per day or distributed over several days [206]. In ICP, therapy with ursodesoxycholic acid should start as soon as possible as it relieves itch, but especially improves fetal prognosis [206].

The administration of UV therapy during pregnancy is not generally contraindicated, but it should be carried out with caution and should be performed when skin lesions are present. It should be limited to late pregnancy and should be performed only after the patient has been provided with thorough information. PUVA therapy with oral psoralen administration is contraindicated.

#### Key points: pruritus in pregnancy

- Pruritus during pregnancy without any skin lesions usually presents as ICP.
- The prevalence of pruritus during pregnancy shows substantial geographical variation.
- There are too few controlled studies investigating treatment for pruritus during pregnancy for conclusions to be drawn.

## Pruritus of unknown origin

### Definition

Itching without any underlying etiology after thorough history-taking and examination of the skin and general examination [21] is termed pruritus of unknown or undetermined [1] etiology. Some authors also use the terms “idiopathic pruritus” and “idiopathic itch.” Pruritus of unknown origin is rare in children but more common in adults, especially the elderly. This type of pruritus is characterized by prolonged persistence, lasting months to years.

### Incidence/prevalence

There are limited epidemiological data on the incidence and prevalence of pruritus of unknown origin. In 132 German patients suffering from pruritus as a leading symptom, it was impossible to identify an underlying etiology in 8% [4]. In 3/84 Ugandan patients (3.6%), the cause of chronic itch was unknown [4]. A study investigating outpatients presenting with pruritus of unknown origin identified an underlying systemic disease in 11 of 50 patients. The cause of itch was unknown in 13/43 (30%) cases of generalized itch [218]. In 34 inpatients admitted for investigation of treatment of generalized itch, three had no etiological factors (8.8%) [219].

Analyzing 74 problem cases of itching revealed 10 unexplained cases (13.5%) [220]. In a German retrospective study of underlying diseases in 263 patients with chronic itch, no disease was found in 44.5% of patients; 55.6% of them, especially elderly patients, had many cofactors contributing to chronic itch, suggesting its multifactorial origin [221].

### Prognosis

According to one clinical study, the prognosis is poorer and the quality of life is significantly more impaired in idiopathic pruritus in comparison with pruritus in dermatological and systemic diseases [4]. A study in 75 patients with pruritus of unknown origin found that 55% of patients reported to be more agitated and 23% were depressed, and 15 (20%) were anxious [222].

### Aims of treatment

Abolition of itching, reducing discomfort, improving the quality of life.

### Relevant outcomes

Abolition of itch.

### Have any effective therapies been reported for pruritus of unknown origin?

#### Evidence summary

Sixty patients with “idiopathic perianal pruritus” were treated either with topical steroids twice daily (methylprednisolone) for 2 weeks ( $n = 28$ ) or with a liquid cleanser twice daily for 2 weeks ( $n = 32$ ). Treatment was effective in 93% of the patients receiving topical steroid treatment and in 91% of those treated with the liquid cleanser. There were no significant differences between the two treatments, suggesting that perianal cleansing is as effective as topical corticosteroids [116]. Fifteen patients with idiopathic anogenital pruritus were treated with paravertebral injections consisting of 2.5 mL triamcinolone and 2.5 mL lidocaine 1% divided into five or six separate injections, with a significant decrease in the mean pruritus scores assessed by the patients before and after treatment [101].

There have been no studies on UV phototherapy in patients with pruritus of unknown origin. UVB or a combination of UVA–UVB phototherapy can be tried, depending on the status of the skin (e.g., UV-light sensitivity, itching of the whole body).

Also, in pruritus of unknown origin, general itch-relieving measures should be applied; for example, avoiding of dryness of the skin, skin moisturizing on a daily basis, use of symptomatic itch-relieving topicals such as polidocanol and menthol. In cases of localized itch, topical immunomodulators and topical capsaicin may be tried. According to recent studies and the European guideline on chronic pruritus, the following therapies may be tried in pruritus of unknown origin: desloratadine up to  $3 \times 10$  mg/day, naltrexone 50–150 mg/day, gabapentin  $3 \times 100$  mg/day to  $3 \times 900$  mg/day, paroxetine 20–40 mg/day [21].

#### Key points: pruritus of unknown origin

- Pruritus of unknown origin has a major impact on a patient's quality of life and mood. Therapy is a challenge in this group of patients, as no effective treatments are available. The available data are insufficient for conclusions to be drawn.

# Vulval lichen sclerosus, erosive lichen planus, and vulvodynia

Rosalind C. Simpson<sup>1</sup>, Ruth Murphy<sup>2</sup>, and David Nunns<sup>3</sup>

<sup>1</sup>Centre of Evidence Based Dermatology, University of Nottingham, Nottingham, UK

<sup>2</sup>Department of Dermatology, Nottingham University Hospitals, Nottingham, UK

<sup>3</sup>Department of Obstetrics and Gynaecology, Nottingham University Hospitals, Nottingham, UK

## Background

Vulval skin conditions have long been a neglected area of research in medicine, resulting in the absence of even basic data such as estimates of disease prevalence. Additionally, it is common for affected individuals to delay seeking medical advice through fear and embarrassment. Finally, through lack of training [1] the medical profession will often fail to fully explore vulval symptoms; women may present to a range of different specialities, and making the correct diagnosis may take considerable time.

Survey-based studies indicate that vulval skin disorders are much more prevalent than once thought. In a survey of 79 UK general practitioners, over half saw more than three patients with vulval disorders per month [2] and a US-based community survey of 303 women reported 18.5% having lower genital tract discomfort lasting longer than 3 months [3].

Vulval skin complaints are important as they cause considerable distress and can affect both physical and psychological well-being [4, 5]. Furthermore, certain inflammatory vulval conditions have potential for progression to malignancy.

Although there are numerous conditions that could be addressed in this chapter, three important disorders that are managed frequently within the vulval speciality clinic have been selected and the evidence for their treatment reviewed.

## Lichen sclerosus

### Definition

Lichen sclerosus (LS) is an inflammatory dermatosis predominantly affecting the anogenital skin in both sexes. It is intensely itchy, often keeping people awake at night, and scratching results in painful fissures. In children, perianal fissures often present as constipation.

Clinical features are usually diagnostic as white papules, plaques and hemorrhage occur in a “figure of eight” distribution around the periclitoral and perianal regions. There is “cigarette paper” thinning of affected skin which will frequently break, resulting in fissures, often in the interlabial sulci. Hyperkeratosis may occur in other

areas. LS only affects keratinized squamous epithelium and, therefore, spares the vagina.

Whilst LS may affect males as well as females, for the purpose of this review the data have only been presented in the context of vulval disease.

### Incidence/prevalence

The true incidence of LS is unknown, although it is the most frequent dermatosis managed in vulval specialist outpatient clinics. Figures between 1/300 and 1/1000 [6] women have been made, but this is likely to be an underestimate. There are two recognized peaks of presentation: one in the prepubertal years and the other in the postmenopausal years [7, 8]. Although childhood LS usually improves, there may be cases that persist into adulthood, and young patients should be managed with this in mind [9].

### Etiology

The pathogenesis of LS is not truly understood. However, autoimmunity is thought to play a part and, in keeping with other autoimmune disorders, LS occurs more frequently in females. It is also associated with other autoimmune disorders [10], particularly thyroid disease [11]. A large observational cohort study of 1000 vulval LS patients showed that 12% had a positive family history of LS, suggesting a genetic or familial clustering effect [12].

### Prognosis

In general, LS responds well to treatment and most women will experience good disease control with improvement of signs and symptoms. Reduction in itch is usually the first symptom to be reported. The clinician will see loss of hemorrhage, reduction in hyperkeratosis, and healing of fissures, although pallor may persist. It should be possible in most cases to avoid scarring, which can result in dyspareunia and difficulty in micturition. Hyperkeratotic variants of LS are particularly associated with squamous cell carcinoma with an estimated risk between 2 and 5% [8, 13]. It is unclear whether better disease control reduces the risk of malignant transformation.

## Diagnostic tests

The diagnosis of LS can usually be made clinically. Guidelines issued by the British Association of Dermatologists for the management of LS suggest that a confirmatory biopsy is ideal, although not always practical [14]; for example, in children, or when disease affects sensitive anatomical areas, such as the clitoris. Histological examination should be made in cases with atypical features if there is diagnostic uncertainty or suspicion of neoplastic change, such as unresponsive disease hyperkeratosis or nonhealing ulceration [14].

## Aims of treatment

Affected individuals should be reassured that, with adequate early treatment, LS can be well controlled with full remission of symptoms and restoration of normal sexual function. The overall aims of treatment are:

- 1 reduction in disease morbidity by reducing itch, pain, and constipation;
- 2 prevention of scarring and maintenance of normal architecture with preservation/restoration of usual sexual function;
- 3 reduction of hyperkeratosis and risk of malignant progression.

## Relevant outcomes

As there are no outcome measure scales specific to vulval skin disease or LS [15], the outcome measures used are those involving a patient-rated change in symptoms and a clinician-rated change in appearance. Specific patient-rated considerations relate to itch, pain, and sexual function. Clinician-directed assessment is reduction in hemorrhage, pallor, and hyperkeratosis.

## Search methods

Medline, Embase and the Cochrane Database of Systematic Reviews/Cochrane Central Register of Controlled Trials were searched from the time of inception up to July 2012. Searches used the MeSH terms “Lichen sclerosus et atrophicus” and “vulvar lichen sclerosus” in combination with the Cochrane collaboration’s filter method for randomized controlled trials (RCTs).

## Questions

### Case scenario 72.1

A 59-year-old female presented with a 6-month history of intractable vulval and perianal itch. On examination there was pallor and hyperkeratosis in a “figure of eight” configuration involving the periclitoral and perianal skin (Figure 72.1). A diagnosis of LS was made.

### What is the evidence for topical treatments in adult vulval lichen sclerosus?

The usual clinical practice for the treatment of LS in adults is to use superpotent topical corticosteroids. There is an emerging literature for the use of topical calcineurin inhibitors. Evidence for the use of topical therapy in LS is considered and the best quality RCTs are described below.

#### Efficacy

##### Topical corticosteroids

A Cochrane systematic review of topical interventions for LS [16] affecting the genital region found some limited RCT evidence for the treatment of LS with topical corticosteroids. In total there was only one study included in the review comparing topical corticos-

**Figure 72.1** LS in a postmenopausal woman showing the classical figure of eight distribution and fissuring in the peri clitoral region.

teroids against placebo, to control the disease in females [17]. In this study, Bracco *et al.* randomized 79 patients with biopsy-proven LS to receive clobetasol propionate, topical testosterone, topical progesterone, or placebo.

Topical clobetasol propionate was used in 20 patients for 3 months against 19 patients in the control group, who received a cream-based placebo. Clobetasol propionate was significantly better than placebo in relation to the following outcomes: “participant-rated improvement or remission of symptoms” (risk ratio [RR], 2.85; 95% confidence interval [CI], 1.45–5.61) and “investigator-rated global degree of improvement” (standard mean difference [SMD], 5.74; 95% CI, 4.26–7.23).

##### Topical hormone preparations

Historically, the role of topical testosterone has been considered as a treatment option for controlling LS. In the same study just described, Bracco *et al.* [17] found that 3 months’ application of testosterone was significantly less effective than clobetasol propionate with regard to participant-rated improvement or remission of symptoms (RR, 0.67; 95% CI, 0.45–0.98) and investigator-rated global degree of improvement (SMD, –1.81; 95% CI, –2.56 to –1.06). No significant differences in adverse drug reactions were found between the testosterone and clobetasol propionate groups.

Topical progesterone 2% was compared against placebo in the study by Bracco *et al.* [17] and was found not to be significantly better for patient- (RR, 1.58; 95% CI, 0.72–3.50) or clinician-related outcomes (SMD, 0.34; 95% CI, –0.29 to +0.97).

In another study, Sideri *et al.* [18] found no significant difference between topical testosterone 2% compared with placebo in 58 women with histologically confirmed LS treated over 1 year.

##### Topical immunomodulators?

There has been one RCT study testing the efficacy and safety of pimecrolimus (1% cream) against clobetasol propionate 0.05% after 12 weeks’ application [19]. Both agents were effective in relieving

pruritis (SMD,  $-0.33$ ; 95% CI,  $-0.99$  to  $+0.33$ ) and burning/pain (SMD,  $0.03$ ; 95% CI,  $-0.62$  to  $+0.69$ ), and there were no significant differences between the two. However, when assessed by the “Investigator-rated global degree of improvement,” pimecrolimus was less effective than clobetasol propionate (SMD,  $-1.64$ ; 95% CI,  $-2.40$  to  $-0.87$ ). There were no adverse drug reactions reported in either group.

There have been no RCTs to date assessing the efficacy of topical tacrolimus in the treatment of vulval LS; however, a case series of 84 patients (49 women, 32 men, and three girls) has supported the efficacy of tacrolimus [20].

### Drawbacks

In both of the RCTs reported [17, 19], both clobetasol propionate and pimecrolimus appeared to be well tolerated with no adverse effects (e.g., predisposition to infection, worsening of skin atrophy, and contact dermatitis) reported.

However, the long-term safety profile of calcineurin inhibitors is not established, and there are concerns about an increased risk of neoplasia with their use in a disease with a pre-malignant potential [21–23]. There are case reports of squamous cell carcinoma developing in patients who have been using these treatments [24, 25], and their long-term use in LS is currently not advised.

### Comment/implications for clinical practice

Trial data about the treatment of LS in adults are still limited, but it would appear that a superpotent corticosteroid (clobetasol propionate 0.05%) should be first-line therapy [17]. There are no RCT trial data for the optimum frequency of application or duration of the steroids; and even the RCTs included different frequency of use of topical steroids: clobetasol propionate 0.05% was applied twice daily for 1 month then once daily for 2 months in the Braco study [17], whereas in the Goldstein trial comparing pimecrolimus and clobetasol propionate [19], clobetasol propionate was applied once daily.

The British Association of Dermatology Guidelines [14] suggest application once daily, at night, for 4 weeks, then on alternate nights for 4 weeks, and then twice weekly for a further 4 weeks, before review. The rationale for once-a-day application is based on pharmacodynamic studies showing that an ultrapotent steroid only needs to be applied once a day on extragenital skin [26]. If symptoms recur when the frequency of application is reduced, the patient is instructed to use the treatment more often until the symptoms resolve. They can then try to reduce the frequency again. A 30g tube of clobetasol propionate 0.05% should last at least 12 weeks [14]. In steroid-resistant disease or cases where there is contact dermatitis, the evidence suggests that calcineurin inhibitors such as pimecrolimus might be efficient and well tolerated [19], but should be used with caution on a short-term basis where possible.

### Case scenario 72.2

A 9-year-old girl presents with a 6-month history of observed rubbing in the genital region. She has also become more constipated with pain on defecation. Clinical findings were in keeping with lichen sclerosus and are shown in Figure 72.2.

### What is the evidence for treating lichen sclerosus affecting children with topical steroids?

#### Efficacy

Whilst in adults it is accepted that superpotent topical steroids should be the first-line choice, there are no ongoing RCTs to base

Figure 72.2 LS in a prepubertal female.

this recommendation in childhood LS. In a case of 70 cases of childhood vulval LS, potent topical corticosteroids were effective treatment to alleviate symptoms, without significant side effects [27]. This has also been reported in two other smaller studies [28, 29].

A small study on the use of pimecrolimus in four prepubertal girls also noted an improvement in symptoms [30]. However, stinging on application was often reported.

### Drawbacks

There are only limited data for the treatment of LS in children with potent topical steroids and calcineurin inhibitors. The use of calcineurin inhibitors was associated with stinging [29]. As with the adult population, there is also the concern that long-term treatment with these drugs could be associated with neoplastic change.

### Comment/implications for clinical practice

The evidence for the use of topical steroids in children is limited. Through the case series evidence available, it would appear that potent topical steroids are effective in the alleviation of the symptoms of LS without obvious side effects [27, 28]. The use of pimecrolimus is also reported, but this is a very small case series of only four girls [30].

## Erosive lichen planus

### Definition

The erosive subtype of lichen planus (ELP) is a chronic, inflammatory disorder that may affect any surface lined with squamous epithelium. In contrast to the non-erosive subtype, which affects mainly the skin, typical areas of involvement include the mucosal surfaces of the oral and genital regions. Of particular note is the “vulvo-vaginal gingival syndrome,” an uncommon, but severe variant concomitantly affecting the vulva, vagina, and gingiva.

## Incidence/prevalence

The true incidence and prevalence of genital ELP is unknown. Studies of patients attending vulval specialty clinics have found that vulval ELP accounted for 3% [31], 5.9% [32], and 8% [33] of all new referrals. In a case series of 3350 vulval biopsies, the prevalence of vulval ELP was 3.7% [34]. These figures indicate that vulval ELP is not so rare as once thought, although this is still likely to be an underestimate of the overall problem.

## Etiology

Current thinking is that autoimmune mechanisms cause basement membrane zone (BMZ) disruption and that vulval ELP is an autoimmune condition [35]. An increased prevalence of autoimmune disorders has been demonstrated in patients with vulval ELP [10], and circulating autoantibodies targeted towards specific BMZ proteins (BP 180) have been located [36]. However, it is not clear if these antibodies are directly pathogenic, or whether they are a result of epitope spread due to BMZ damage from another cause.

## Prognosis

Unlike classical (non-erosive) LP, which is self-limiting and responds well to therapy, vulval ELP takes a relapsing–remitting, chronic course and is often treatment resistant. Scarring is common and causes anatomical destruction with loss of function (such as micturition and sexual activity). Vulval ELP is thought to have malignant potential, with an estimated 3% of cases developing squamous cell carcinoma [37].

## Diagnostic tests

The diagnosis of vulval ELP is made clinically with appropriate histopathological correlation. This is largely due to the nonspecific histological features found on biopsy and the differential diagnosis of erosive lesions in the vulval region, including intraepithelial neoplasia and bullous disease [6, 38, 39]. Typical clinical findings include well-demarcated introital erosions/erythematous areas (plus/minus hyperkeratotic white edge), which may be seen in combination with similar vaginal lesions. There may also be evidence of scarring with loss of the labia minora, as well as evidence of other affected sites, such as the oral cavity.

Histopathological findings are variable and around 25% will show nonspecific features, especially if taken from eroded areas. The most characteristic lichenoid changes are found when a biopsy is taken from the edge of the lesion, particularly at a hyperkeratotic white margin [40]. It is important to consider secondary infection or associated autoimmune disease when there is a poor response to therapy, and biopsy should be performed in atypical cases or where there is diagnostic doubt.

## Aims of treatment

Treatment aims are:

- 1 reduction in disease morbidity through improving symptoms (mainly pain);
- 2 prevention of scarring and maintenance of normal architecture with preservation/restoration of usual sexual function;
- 3 reduce the risk and monitor for signs of malignant progression.

## Relevant outcomes

Affected individuals are clinically assessed for disease impact and severity, but the therapeutic ladder is driven by the patient response to therapy and how they report their symptoms [41]. As such,

outcomes important in clinical practice are mainly *patient-oriented* and include reduction of symptoms and improvement in health-related quality of life (HRQoL). Clinical outcomes are assessed by the clinician and include the reductions of erythema, erosions, and pain on Q-tip pressure. Currently, there are no vulval or ELP-specific outcome measure scales available [15].

## Methods of search

Medline, Embase and the Cochrane Database of Systematic Reviews/Cochrane Central Register of Controlled Trials were searched from the time of inception up to June 2012, using the key terms “vulva” and “lichen planus”. Because of the lack of controlled studies in this area, evidence from open studies and case series were also reviewed.

## Questions

### Case scenario 72.3

A 58-year-old female presents with a 3-month history of vulval soreness and pain on sexual intercourse. Self-medication with topical antifungal agents had been unsuccessful. Examination revealed well-demarcated introital erosions with a hyperkeratotic white border (Figure 72.3).

### What is the evidence for topical treatments in vulval erosive lichen planus?

Usual clinical practice for the treatment of vulval ELP is to use superpotent topical corticosteroids [42]. There is an emerging literature for the use of calcineurin inhibitors [43–45]. The evidence for the use of topical therapy is considered below.

## Efficacy

### Topical corticosteroids

In general, there is a lack of good-quality trial data for ELP. A Cochrane systematic review of interventions for ELP affecting mucosal sites [46] found no RCT evidence for vulval ELP. Of 15 studies which were included in the Cochrane review, all were for *oral* ELP. There was no overwhelming evidence for the efficacy of a single treatment in the oral subgroup, including topical steroids, which are the current accepted first-line therapy.

**Figure 72.3** Well-demarcated vulval introital erosions with a hyperkeratotic white border.

A subsequent systematic review and meta-analysis of treatments for LP (both cutaneous and mucosal subsets) [47] has been reported in a conference abstract. Of the 54 identified RCTs involving mucosal LP, only one was for vulval disease; the rest were in patients with oral disease. The authors commented upon a lack of clear and accurate measurements of disease outcome or severity. They were unable to perform a meta-analysis of RCTs for mucosal LP, although they did comment that, from the meta-analyses included in their review, the potent topical corticosteroids betamethasone valerate and fluocinolone are more beneficial than placebo for *oral* ELP. However, no figures were given to back up this claim, and as this is a conference abstract with limited information it has not been possible to appraise the methods used for the search.

Only one *prospective* case series documenting response to topical corticosteroids was found. Cooper *et al.* [37] followed 114 adult women with definite clinical diagnosis of ELP of the vulva for a mean duration of 72 months. Within this group, the most frequent first-line therapy given was clobetasol propionate 0.05% ( $n = 89$ ): 84/89 showed symptomatic improvement and 63/89 became symptom-free during treatment. Interestingly, symptomatic improvement did not correlate with clinical improvement and, overall, only 10/114 patients had complete resolution of clinical signs with treatment. Other *retrospective* case-series have shown *partial* response to superpotent topical steroids [48, 49].

#### Topical immunomodulators?

One *prospective* case series has specifically looked at the effects of topical pimecrolimus in 11 women who had not responded to topical corticosteroids [45]. Following twice-daily application of pimecrolimus for 4–6 weeks, 2/11 showed complete resolution of symptoms and 7/11 showed partial response. Pimecrolimus was found intolerable in 2/11.

There were seven patients treated with topical tacrolimus and one with topical pimecrolimus in the case series reported by Cooper *et al.* [37]. Response was reported as “good” in two, “partial” in four, and “poor” in two of these patients.

Other *retrospective* case series have reported a mixed response to topical immunomodulators [32, 44]. In a retrospective review of the use of topical tacrolimus in patients with vulval ELP who had “recalcitrant” disease and had failed at least topical corticosteroids (potency unclear), 15/16 patients were “much” or “somewhat” better after twice-daily application for 3 months [44]. In contrast, Helgesen *et al.* [32] only reported complete response in 3/22 and partial response in 6/22 patients to topical tacrolimus. The remaining 13 showed no response. It is not clear which prior treatments patients had received or how long their therapy was given in this study.

#### Intravaginal steroid enemas?

A single-center, nonrandomized, retrospective cohort study assessed the effects of hydrocortisone 25 mg suppositories b.i.d. (subsequently tapered off to achieve a symptom-free maintenance dose) in 60 patients with *vaginal* ELP [50]. Complete response data were only available for 43 patients. Overall symptomatic improvement as reported by the patients was as follows: 58.1% improved; 23.3% “somewhat” improved; 16.3% were unchanged; and 2.3% were worse.

#### Other topical treatments

In the *only* RCT identified by the literature search, *Aloe vera* gel was compared against placebo in 34 women with vulval ELP [51]. It was

reported that 14/17 (82%) of patients showed complete or good response to *Aloe vera* gel compared with 1/17 (5%) in the placebo group ( $P < 0.001$ ). However, this was a poorly reported study and a number of key factors were not clear, such as the method of randomization, concealment of allocation, or baseline characteristics in each of the groups. Furthermore, there was no intention-to-treat analysis, no flow diagram of participants, and the outcome measures used was a score designed for *oral* ELP (the “Thongprasom score”).

#### Case scenario 72.4

A 63-year-old female presented with a 2-year history of ELP affecting the oral and genital mucosa. Response to topical therapy had been poor. She had evidence of genital scarring with loss of the labia minora and introital narrowing (Figure 72.4). She reported ongoing vulval pain and burning, leading to a loss of sexual function.

#### In erosive lichen planus affecting the vulva that is unresponsive to topical treatment, what is the evidence for systemic treatment?

##### Efficacy

The only evidence found describing the effects of systemic therapy in ELPV were case series and case reports. The case series with the largest number of patients was by Hubbard *et al.*, who document the effects of hydroxychloroquine [52] in 17 patients. A 12-month course of hydroxychloroquine was completed by 15 patients, 13 of whom showed “good” symptomatic improvement. These results were reported in a conference abstract, and outcomes were measured by a “severity” index devised by the authors.

Pelisse [40] reported a good response to oral prednisolone in 10 patients with the vulvo-vaginal gingival syndrome.

Numerous other systemic therapies have been reported upon, either as single case reports or as part of a larger case series.

**Figure 72.4** Advanced ELP with scarring causing loss of normal architecture. Well-demarcated erythematous erosions are present.

However, numbers were all in single figures, and conclusions cannot be drawn from these articles. In their prospective case series, Cooper *et al.* [37] comment that “systemic treatments were surprisingly unhelpful, with a uniformly poor response to systemic immunosuppressants”; however, prednisolone, ciclosporin, and azathioprine had only been given to three, two, and one patient, respectively.

## How effective is surgical intervention to treat scarring?

### Efficacy

Again, only retrospective case series and case reports were available. The largest number of patients were documented by Helgesen *et al.* [32], who reported “good” response in 13/17 patients who underwent dilatation procedures in conjunction with topical steroids. However, relief was to a varying degree, often with some recurrence.

### Drawbacks

Adverse events were not commonly reported in the studies reviewed. Byrd *et al.* reported irritation from topical tacrolimus in 6/16 patients [44], and from Lonsdale-Eccles and Velangi’s case series [45] 2/11 patients (18%) were unable to tolerate pimecrolimus owing to local irritation. Topical immunomodulators have received attention for their theoretical potential to cause infection or contribute to the development of malignancy, although no good evidence to support this in vulval skin was found.

### Comment/implications for clinical practice

The most widely accepted first-line therapy for vulval ELP is superpotent topical steroids. However, as demonstrated by the Cochrane review, there is no RCT evidence to support this, or any other treatment modality in the management of the disease. Although the other systematic review identified two potent topical steroids were effective for oral ELP, data for this were lacking as it was a conference abstract. Both reviews commented upon the lack of validated and standardized outcome measures for mucosal ELP.

The case series identified were mainly retrospective. Diagnostic criteria for inclusion of participants and outcome measures used varied widely and were not validated in any way. It is difficult, therefore, to compare datasets, particularly as the method of reporting outcomes was so different. The most comprehensive case series to date [37] indicates that superpotent topical steroids are an effective first-line therapy in around 70% of patients. In the absence of any other evidence, it is reasonable to believe that these should be used as first-line therapy in clinical practice.

The evidence for second-line therapy is severely lacking, even through case series. Responses to treatment with anti-inflammatory and immunosuppressant agents are therefore given on an anecdotal basis at present, and there is an urgent need for controlled trials in this area. Since vulval ELP is a chronic disease, any clinician prescribing systemic therapy should balance the risk of long-term disease control against the potential side effects of the use of the drug.

## Vulvodynia

### Definition

Vulvodynia has been defined by the International Society for the Study of Vulval diseases as vulval discomfort, most often described

as a burning pain, occurring in the absence of relevant visible findings or a specific, clinically identifiable, neurologic disorder [53]. The pain of vulvodynia may be localized or generalized, and spontaneous or provoked by touch or pressure on the vulva; for example, during the insertion of sanitary protection, sexual intercourse, or even on wearing clothes. Vulvodynia is a neuropathic pain condition, and on examination there is no evidence of a dermatological problem. The term “vestibulodynia” describes provoked pain localized to the vestibule region, with pain experienced on sexual and nonsexual touch. Clinically, this can be demonstrated using a cotton-tipped swab when applying gentle pressure to the vestibule area. The maximal area of tenderness is experienced over the entrance to the Bartholin’s glands [54]. Some patients may have a combination of vulvodynia with another vulval problem (e.g., herpes or thrush), and both conditions may require treatment. As the condition is frequently chronic, a high level of psychological morbidity is common. Some patients are prone to stress and anxiety, which may play a role in developing symptoms [55]. Sexual dysfunction is common and frequently reported [56]. Reduced sexual arousal, more negative sexual feelings, and less spontaneous interest in sex (not elicited by a partner) have all been described in vestibulodynia [57]. These are all risk factors for significant psychosexual dysfunction, such as vaginismus and anorgasmia, the management of which usually requires psychosexual input.

### Incidence/prevalence

The incidence in the UK remains unknown. However, the prevalence of vestibulodynia was 1.3% of women attending a central London genitourinary medicine clinic [58]. It is likely that patients are misdiagnosed.

### Etiology

This remains unknown, but is likely to be multifactorial. It is often difficult to identify a cause, as symptoms usually develop insidiously. Recurrent attacks of vulvovaginal candidiasis have been suggested as a cause [59].

### Prognosis

Up to 30% of women with vestibulodynia may experience resolution of their symptoms without treatment, and in 50% of these resolution can occur within 12 months [60]. The prognosis for unprovoked vulvodynia remains unclear.

### Diagnostic tests

Vulvodynia is diagnosed clinically without the need for diagnostic skin biopsies. It remains important to ensure that dermatological conditions of the vulva are excluded before making such a diagnosis of vulvodynia. In a paper by Bowen *et al.* [61], 61% of patients with “vulvodynia” actually had a relevant dermatological condition of the vulva and were rediagnosed after a biopsy.

### Aims of treatment

Treatment aims are:

- 1 reduction in pain, improved function;
- 2 if appropriate, increase satisfactory pain-free sexual intercourse.

### Relevant outcomes

Affected individuals are clinically assessed for the severity and level of pain and its impact on function. The therapeutic ladder is driven by the patient response to therapy from a pain and/or psychosexual

perspective. As such, outcomes important in clinical practice are mainly *patient-oriented* and include reduction of symptoms and improvement in HRQoL. A variety of pain management scores are available, such as the Brief Pain Inventory.

### Methods of search

Medline, Embase, and the Cochrane Database of Systematic Reviews/Cochrane Central Register of Controlled Trials were searched from the time of inception up to June 2012, using the key terms “vulvodynia” and “vulval pain syndromes.” Because of the lack of controlled studies in this area, evidence from open studies and case series were also reviewed.

## Questions

### Case scenario 72.5

A 28-year-old female presents with a 9-month history of localized provoked vulval pain. Pain was experienced with tampon use and during cervical smear taking. Examination of the vulva was normal, but there was sensitivity over the vestibule area when touched with a cotton bud.

### What is the evidence for treatments in localized provoked vulvodynia (vestibulodynia)?

A body of evidence now suggests that the management of patients with vestibulodynia is to desensitize the vulval area, as sexual pain is the main complaint. Many women will have secondary vaginismus (involuntary contraction of the pelvic floor muscle) in response to the touch sensitivity (allodynia).

### How effective is psychological and psychosexual therapy in the management of vestibulodynia?

#### Efficacy

Patients with provoked pain (vestibulodynia) may benefit from a psychological approach initially. In one RCT, 78 women with provoked pain were randomized to one of three arms: group cognitive behavioral therapy (for 12 weeks), pelvic floor biofeedback (for 12 weeks), and vestibulectomy [62]. At 6-months' follow-up, all patients reported improvements in pain scores, although there was no significant difference between groups. The study supported both forms of nonsurgical treatment and suggested that patients prefer a behavioral approach to treatment than a surgical one.

### How effective is physical therapy in the management of vestibulodynia?

#### Efficacy

Physical therapy techniques are first-line treatments used to desensitize the vulva. They help reverse an apparent hypertonicity in the levator ani (pelvic floor muscles) and help patients overcome a phobia of genital touch. A variety of physical therapies have been reported to show benefit, including pelvic floor muscle biofeedback, self-massage of the vulva, vaginal transcutaneous electrical nerve stimulation, and the use of vaginal trainers [63–65]. No studies have reported an optimal technique, and success depends on several factors, including the therapist, degree of patient support, and duration and number of sessions. Biofeedback therapy has been used successfully to help overcome pelvic floor muscle dysfunction in women with provoked vulvodynia, with response rates of 52% [63].

### How effective are intralesional injections in the management of vestibulodynia?

#### Efficacy

There is some evidence that intralesional injections into the vulva may be of benefit in patients with provoked vulvodynia, and various drugs have been suggested. Murina *et al.* [66] gave subcutaneous injections of 40 mg methylprednisolone acetate and 10 mg of lidocaine hydrochloride in 10 mL of normal saline into the vestibule in 22 women with vestibulodynia. Follow-up was for a period up to 2 years. In their results they state that 15 women (68%) responded “favorably” to the treatment and 32% experienced complete remission, which occurred about 15 days after treatment. It is worth noting that these favorable results are comparable with those achieved with less invasive, and less time-consuming (for the patients) options. Similar positive results were obtained in trials looking at betamethasone and lidocaine infiltration [67, 68].

### Case scenario 72.6

A 60-year-old female presented with a 4-year history of unprovoked vulval burning and soreness. Her discomfort restricted her socially and she had tried a variety of topical medications without success. Clinical examination of the vulva was normal.

Patients with unprovoked vulval pain are akin to other patients with neuropathic pain and should be managed along similar lines. Sexual pain is less of a problem in this group, and chronic pain management to focus on a reduction in the severity of the pain is a key issue.

### How effective are pain-modifying drugs in the management of unprovoked vulvodynia?

#### Efficacy

There are no RCTs to demonstrate the optimal pain-modifying drug for unprovoked pain. Tricyclic antidepressants, gabapentin, and pregabalin have shown benefit in the treatment of unprovoked vulvodynia in some small cohort studies [69–71]. Complete responses at 6 months of 47% have been reported [72].

It should be noted that, for patients with provoked vulvodynia, the benefit of drugs such as tricyclic antidepressants and gabapentin is less clear, and these would not be considered first-line treatment.

### How effective are topical anesthetics in the management of unprovoked vulvodynia?

#### Efficacy

Topical local anesthetics, such as 5% lidocaine gel or ointment, are commonly prescribed for women with vulvodynia. One RCT found a 33% response rate for placebo compared with 20% for topical lidocaine in women with vestibulodynia, but this was not significant [73]. In addition, local anesthetics are potent sensitizers and should be used with caution on the vulva because they can lead to allergic contact dermatitis.

### Drawbacks

With the exception of the trial by Foster *et al.* [73], all studies lack a placebo-controlled arm and there is a clear need for RCTs focusing on specific subgroups of women with vulvodynia and clear outcomes. Most of the studies are small with inadequate follow-up duration. In addition, treatments are often given in isolation and would be best used in combination.

### Comment/implications for clinical practice

The optimal treatment package is a multidisciplinary approach with the clinician assessing the patient, making a diagnosis, and starting

basic management. Referral to other health professionals (e.g., for psychosexual counseling, pain management, and physiotherapy) may be necessary depending on the individual needs of the patient. Recently, the British Society for the Study of Vulval Diseases published evidence-based guidance on the management of women with vulvodynia recommending this multidisciplinary approach [74]. As dermatologists are seeing patients at the initial referral, it may be appropriate for them to triage these patients and remain as a “lead” for those patients who might need to see two or three different health professionals to address the different aspects of the patient’s complaint. Patients frequently complain that their care is disjointed, and a lead clinician to coordinate care is helpful.

## CHAPTER 73

# Venous ulcers

Jonathan Kantor, David J. Margolis, and Douglas J. Pugliese

Department of Dermatology, Perelman School of Medicine at the University of Pennsylvania, Philadelphia, PA, USA

### Background

#### Definition

Venous ulcers are wounds that usually occur in a gaiter distribution of the lower leg (Figure 73.1). They are associated with increased pressure in the superficial venous system of the lower legs during ambulation (ambulatory venous hypertension) and are possibly related to several pathophysiologic mechanisms including failure of the calf muscle pump to return venous flow effectively [1], dysfunction of valves in the superficial and/or communicating veins, dysfunction of valves in the deep venous system, and/or deep venous outflow obstruction [2–4].

#### Incidence/prevalence

Venous leg ulcers are common with an incidence in people over 65 years of age in the UK of 0.76 (95% confidence interval [CI], 0.71–0.83) per 100 person-years for men and 1.42 (95% CI, 1.35–1.48) for women [5].

#### Etiology

There are several hypotheses that have been proposed to explain the pathogenic steps that are necessary for venous hypertension or venous insufficiency to lead to venous ulceration. In a diseased venous system or failure of the calf muscle pump, venous pressure in the deep system upon ambulation may either fall minimally or not at all [6]. Ultimately, venous hypertension in the deep veins may be transmitted to the superficial system [3,7,8]. Although venous ulcers can occur in patients with only perforator or superficial vein incompetence, they are usually associated with deep venous insufficiency [9,10]. It has been hypothesized that ambulatory venous hypertension leads to ulceration and failure to heal because of senescence of cells in the wound, white blood cell trapping in the microcirculation, fibrin cuffing of the microcirculation, trapping of growth factors and other homeostatic substances in the dermis

disturbing tissue integrity, abnormalities of coagulation cascades, and other mechanisms [1,6,11–15]. Unfortunately, none of these hypotheses has been shown to universally explain why a wound occurs and poorly heals.

#### Risk factors

Most epidemiologic studies on chronic venous insufficiency have recognized several risk factors for venous ulceration including older age, obesity, significant leg trauma, heart disease, congenital absence of valves, previous surgery of varicose veins, primary valve or venous wall degeneration, arteriovenous shunts, and type of employment [16,17]. The degree and pattern of venous insufficiency are also predictive of the development of ulcer formation [18,19]. Insufficiency of the superficial and perforating veins in combination carries a greater risk than insufficiency of the superficial veins alone [4]. There is also a well-recognized association between deep venous thrombosis and venous ulceration [20]. Individuals with venous leg wounds often have varicose veins and other cutaneous findings consistent with venous disease, as well as other medical diseases, such as atherosclerotic vascular disease and diabetes, that can complicate the clinical picture [1,21–23].

#### Prognosis

Venous leg ulcers do not generally lead to the need for amputation, but often result in chronic, malodorous wounds that dramatically impair the quality of life of those afflicted with them. Many venous ulcers heal within 24 weeks of care, but the proportion healed after 24 weeks varies widely in the medical literature. Several studies have shown that the initial healing rate and the percentage change in the venous leg ulcer area in the first 4 weeks of treatment was predictive of complete healing [24–26]. It is important to note that while several studies have shown a peak prevalence between 60 and 80 years of age for venous ulcer disease, 22% of venous ulcer patients will have their first ulcer by age 40 [27–30]. Thus, venous

**Figure 73.1** Venous ulcer of the lower extremity (case scenario 73.1).

ulcers can have a tremendous impact on work productivity and premature disability [30,31]. Some studies have shown that, once diagnosed, the majority of patients will have a recurrence and many will have a long ulcer duration of greater than 1 year [29].

### Aims of treatment

The aims of treatment are to improve the rate of healing and to increase the likelihood that a patient will heal over a given period of time (often 12–24 weeks). Multiple different guidelines have been published by different medical societies for the treatment of venous ulcers [32,33].

### Relevant outcomes

Relevant outcomes include the proportion of wounds healed by the end of the study and the rate of healing.

### Methods of search

Medline, Embase, and the Cochrane Database of Systematic Reviews were searched for the terms “venous ulcer” and “heal” or “treat,” as well as bibliographies of relevant articles and systematic reviews.

## Questions

### What therapies are effective for treating venous leg ulcers?

#### Case scenario 73.1

A 56-year-old woman has an ulcer 25 cm × 6 cm on the medial side of the left ankle (Figure 73.1). The ulcer's red base is covered with yellowish fibrinous debris. On the edges are some signs of reepithelialization. The left lower leg was edematous before use of a limb compression stocking. The limb shows signs of chronic venous

insufficiency: pigmentation, enlargement of the cutaneous veins, and fibrosis. What therapies would be effective treatments?

## Compression

### Benefits

Compression of the lower extremity is one of the oldest and most widely used treatments for venous ulcers. Compression aids venous return, and different methods include stockings, single and multi-layer bandages (both elastic and inelastic), and pumps.

An updated Cochrane collaborative review has evaluated the role of compression in the treatment of venous ulcers [34]. This review included 39 trials using a number of different compression methods. Seven trials compared compression with no compression, and demonstrated that venous ulcers heal more rapidly with compression than without. Of these, two trials evaluated compression using an Unna boot versus no compression. Both studies demonstrated a benefit of compression. Five additional studies compared compression bandages with noncompressive bandages or usual care and demonstrated a benefit. Findings from six trials of single-component compression suggested that this strategy was less effective than multicomponent compression. Seven trials with evidence of using two-component and three-component compression systems showed better outcomes when an elastic component was included. Evidence from three trials with different versions of compression with four-component systems suggested similar effectiveness, but it was difficult to compare the four-layer bandage with the Unna boot because of differences in the paste systems. The four-layer bandage was found to be more clinically effective than multicomponent systems comprising a short-stretch bandage. It is important to point out that in another study not included in the Cochrane review, in a subgroup of the hardest to heal patients, the four-layered bandage was superior [35].

This Cochrane collaborative review did assess cost data that had been included in seven trials and found only one study suggesting that the four-layer bandage was more cost-effective. Several trials assessed health-related quality of life and pain, either as a stand-alone outcome or as part of the assessment of adverse events, and there were no differences found between treatment groups.

### Complications

Complication rates are not usually noted in trial reports, partly because compression therapy is generally benign. Inexpertly applied high compression could lead to soft tissue damage, the development of additional wounds, and potentially amputation, although the chance of this occurring is remote.

### Comment

Compression has been the mainstay of therapy for venous ulcers, and with good reason. It is clear that the overall take away from the medical literature is that compression is superior to no compression in treating venous ulcers. In addition, multicomponent systems are more effective than single-component systems, and multicomponent systems appear to perform better when they are mainly composed of elastic constituents. The method used to apply these bandages is important, and there is some suggestion that the ability to apply compression bandages effectively varies widely. Compression therapy should not be used in patients with an impeded blood supply to the lower extremities. Finally, it is important to note that, in all of these studies of compression, the selection of the bandage directly applied to the wound at a minimum

is to maintain it in a moist state. Very few quality randomized studies exist that compare wound bandages, and this topic is beyond the scope of this chapter. In addition, in practice, health-care providers often change their choice of wound bandage during the course of therapy depending on the properties of the bandage and the wound's status.

### **Implications for clinical practice**

Compression represents the cornerstone of the clinical management of patients with venous ulcers. Most studies evaluating novel therapies for venous ulcers use compression as the standard care regimen (Level I).

## **Pentoxifylline**

### **Benefits**

Pentoxifylline is a trisubstituted xanthine derivative that has been used to treat a variety of systemic disorders, most notably intermittent claudication. Theoretically, its beneficial effects in vaso-occlusive disease could extend to therapy for venous ulcers. A Cochrane collaborative review has addressed the efficacy of pentoxifylline for the treatment of venous ulcers [36]. Twelve trials, including 864 patients, were included in the Cochrane review. Of note, only seven of the trials included compression therapy in both the pentoxifylline and placebo groups. Combining the data from the 11 trials that compared pentoxifylline (in varying doses) with placebo, pentoxifylline demonstrated a beneficial effect. Most of the studies used the probability of healing by 24 weeks as the end point. The relative risk of healing with pentoxifylline versus placebo was 1.70 (95% CI, 1.30–2.24). A separate examination of just the trials that compared pentoxifylline plus compression with placebo plus compression also showed a benefit of pentoxifylline therapy with a relative risk of 1.56 (95% CI, 1.14–2.13). Finally, pentoxifylline in the absence of compression appears to be more effective than placebo or no treatment with a relative risk of 2.25 (95% CI, 1.49–3.39).

### **Complications**

Pentoxifylline therapy is associated with an increased risk of side effects, mostly gastrointestinal in nature. These side effects seemed to be tolerated by participants in the studies.

### **Comment**

The Cochrane review authors conclude that pentoxifylline is beneficial either as an adjuvant treatment for venous ulcers with compression or alone where compression cannot be used. It should be pointed out that all the studies included in the meta-analysis did not individually show statistical significance. The dose of pentoxifylline was 400 mg three times daily in all the studies except for one. Even though a beneficial effect in comparison with placebo was noted when limb compression was not used with pentoxifylline, patients treated with pentoxifylline should be treated with compression therapy as well, because limb compression therapy has been shown to increase the baseline chance of healing.

### **Implications for clinical practice**

Pentoxifylline has been shown to increase the relative risk of healing by 50% over compression therapy alone [36]. Clinicians must ultimately decide whether this potential benefit is worth both the practical and the financial cost of pentoxifylline (Level I).

## **Skin grafting**

### **Benefits**

Most venous ulcers respond well to compression therapy. However, some wounds fail to heal with compression therapy alone. One of the options available to the health-care provider is to treat the wound with a skin graft. Grafts can include full-thickness, partial-thickness, allogeneic (cultured), xenografts, and artificial skin (skin equivalent) grafts.

The use of skin grafts for the treatment of venous ulcers is the subject of a Cochrane collaborative review [37]. Overall, 17 trials were identified. Eleven of these trials compared a graft with standard care in which no graft was used. Two trials evaluated split-thickness autografts, six trials evaluated cultured keratinocyte allografts, two compared artificial skin (bilayered skin equivalent) with a dressing, and two compared a single-layer dermal replacement with standard care. The other six trials compared alternative skin grafting techniques. The authors concluded that bilayer tissue-engineered skin replacement, used with compression, increases the rate of healing of venous leg ulcers compared with simple dressings used with compression. They found insufficient evidence for the effectiveness of any other skin graft material or procedure.

It is important to note that 15 of the 17 trials included in this review were underpowered, so that clinically important differences were unlikely to reach statistical significance and be detected. Overall, there were significant concerns regarding the quality of the trials included and this affected the conclusions that the authors could make. In two more recent studies in which patients had venous ulcers refractory in nature to standard care, a heal rate of at least 50% was achieved after skin grafts [38,39].

Graftskin (Apligraf) is a bilayered skin equivalent that includes both dermal and epidermal components. Some health-care providers also call this “artificial skin.” It is manufactured by harvesting neonatal foreskins and extracting both keratinocytes and fibroblasts, which are then separately cultured to create the epidermal and dermal components, respectively. Graftskin has been studied for the treatment of venous leg ulcers. In a study that enrolled 240 patients, the percentage of ulcers healed after 24 weeks was significantly higher in those treated with Graftskin plus standard care (compression) than in those treated with compression alone (57% vs 40%) [40]. Notably, secondary analyses evaluating the relative efficacy of Graftskin in wounds of more than 1 year's duration demonstrated that the benefit of Graftskin was most significant for patients with older wounds (47% vs 19%) [40,41]. Among patients with wounds of less than 1 year's duration, there was no statistically significant difference in the percentage healed after 24 weeks between those treated with Graftskin and those treated with placebo (66% vs 73%) [40,41]. The Cochrane group analyzed these trial data and concluded that the relative risk of healing with artificial skin versus standard dressings was 1.51 (95% CI, 1.22–1.88) [37].

A single multicenter randomized control study also compared the use of porcine extracellular matrix graft (OASIS Wound Material) and a compression bandage with a compression bandage alone [42]. At 12 weeks, significantly more patients in the extracellular matrix group healed (55% vs. 34%;  $P = 0.02$ ).

In a recent phase 2 double-blind randomized placebo-controlled clinical trial, researchers studied a new cellular therapy (HP802-247) based on human growth-arrested neonatal allogeneic fibroblasts and keratinocytes applied with a modified fibrin spray [43]. The study included 228 adults from 28 centers and found a 16% greater reduction in wound size on average compared with vehicle alone at 12 weeks. It also found that 70% of wounds closed in the

treatment group compared with 46% in the control group. All subjects received four-layer compression bandages.

### Complications

A risk of infection, bleeding, and other tissue damage is inherent in any autologous skin grafting procedure. Moreover, there is always an inherent risk that the donor site will prove difficult to heal as well.

Using cultured autologous keratinocytes is likely to delay treatment, because it takes several weeks for the cells to be cultured. Moreover, patients need to undergo a skin biopsy in order to provide the laboratory with the necessary cells.

Artificial skin theoretically could be cultured from samples that are infected with viruses, including human immunodeficiency virus (HIV). Given the aggressive screening associated with this harvesting, however, the chance of infection is remote, although it does remain a possibility that the allogeneic human cells were taken from an HIV-positive but seronegative donor [40].

### Comment

While autologous skin grafts are occasionally used in some centers to aid the closure of recalcitrant wounds, the difficulties associated with harvesting the donor graft, as well as the complexities associated with inducing closure of the grafted site (in addition to the donor site), mean that this procedure cannot be undertaken lightly. Similarly, use of autologous cultured keratinocytes is a time-consuming, expensive, and complex process that demands multiple patient visits and a laboratory capable of culturing the autologous keratinocytes.

Artificial skin for the treatment of venous ulcers is not in widespread use. This may be because of the substantial cost involved. This concern has been addressed in an economics study [44].

### Implications for clinical practice

Standard treatment with infection control, primary dressings, and the application of high-strength compression heals between 30 and 75% of the venous leg ulcers [34]. While most clinicians would not treat all venous ulcers with skin grafts, patients who have wounds recalcitrant to standard treatment could be considered for skin grafts as an adjunct, to improve their likelihood of healing. Of the available skin grafting methods, the use of artificial skin appears to be the most promising, conferring a 29% increase in the likelihood of healing by 24 weeks and an increased rate of healing. These results are based on a randomized controlled trial in patients with recalcitrant venous ulcers [40,41]. However, the short shelf-life of many of these products, the significant costs associated with the therapies, and the theoretical risk of viral infection mean that clinicians need to think carefully before treating patients with artificial skin (Level I).

## Vitamins and minerals

### Benefits

Few practitioners dispute the importance of adequate nutrition for promoting wound healing. However, despite the assumption that vitamin and mineral supplements may aid in healing these wounds, few studies have addressed the potential benefits of supplementation in a rigorous fashion. For example, vitamin C supplements are often prescribed for patients with chronic wounds. Reports evaluating the use of vitamin C as an adjunctive wound-healing agent have

failed to demonstrate a clear benefit of vitamin C supplements in patients with chronic wounds of all types [45,46].

Zinc has been used for more than a century as a topical adjunct for the care of chronic wounds, and Unna incorrectly believed that it was directly responsible for efficacy of his compression bandage. Oral zinc for the treatment of venous ulcers has been addressed in a Cochrane collaborative review evaluating six trials of oral zinc therapy, most of which failed to show a beneficial effect of therapy [47]. Five of these studies included patients with venous ulcers. The doses of zinc varied across studies. One study failed to demonstrate a significant benefit of oral zinc therapy, with a relative risk of healing of 1.5 (95% CI, 0.28–7.93). The remaining studies also failed to show any benefit of zinc therapy.

Topical zinc was evaluated in one study, suggesting improved healing in both arterial and venous ulcers. However, a study in porcine skin suggested that the only beneficial action of zinc on the wound bed was that it inhibited bacterial growth [48].

Several studies have addressed the efficacy of rutosides in decreasing the edema associated with venous insufficiency [49]. Physiologically, it is believed that these agents protect the microcirculation from the increased pressures of ambulatory venous hypertension, thereby preventing edema. A meta-analysis of four studies was published that evaluated a micronized purified flavonoid fraction (MPFF) of *Rutaceae aurantiae* (Daflon) [49]. Basically, 500 mg of MPFF was administered orally twice daily for 2–6 months, which improved the likelihood of a venous leg ulcer healing by about 32% [49].

One case-control study of 85 patients from Brazil looked at the prevalence of vitamin D deficiency in those with venous leg ulcers compared with a control population. They found a higher prevalence of vitamin D deficiency in patients with chronic venous leg ulcers than in controls. The authors admit that more studies need to be done before drawing conclusions [50].

### Complications

There are few side effects associated with vitamin or mineral therapy for venous ulcers.

### Comment

There is a lack of supporting evidence for the supplementary use of vitamin C, zinc, or vitamin D. No studies have effectively evaluated the role of daily multivitamins in patients with chronic wounds. Rutosides may be helpful in edema reduction.

### Implications for clinical practice

Vitamin supplementation is common and relatively benign. Reasonable evidence exists to support the use of rutosides (Level I).

## Ultrasound, laser, and electromagnetic therapy

### Benefits

Laser therapy using a variety of different lasers, ultrasound, and electromagnetic therapy have been proposed as adjunct treatments for venous leg ulcers. Low-level lasers, ultrasound, and electromagnets have been shown to stimulate cellular function, leading to increased protein synthesis and fibroblast and macrophage proliferation.

Ultrasound, laser therapy, and electromagnetic therapy for venous ulcers are the subject of Cochrane collaborative reviews including eight, four, and three trials, respectively [51–53]. None of

the ultrasound studies found a statistically significant treatment effect [52]. In addition, a more recent randomized controlled trial looking at the use of weekly, low-dose, high-frequency ultrasound during dressing changes for hard-to-heal ulcers in addition to standard care did not increase ulcer healing rates [54]. The results of the laser studies were pooled in the Cochrane review and failed to demonstrate a significant benefit of laser therapy, with a relative risk of 1.21 (95% CI, 0.73–2.03) [53]. The results of the electromagnetic therapy also did not demonstrate a statistically significant benefit [51]. However, these are all active areas of research. This is especially true for electromagnetic therapy, where it is also important to note that not all modalities use the same type, dose, or duration of electromagnetic field.

### **Complications**

Complications occur very rarely with these therapies when therapy is administered by well-trained and experienced staff.

### **Comment**

There is some suggestion that laser therapy and electromagnetic therapy may have an effect on end points other than chance of healing; for example, pain at the wound site and the amount of granulation tissue. The use and meaningfulness of these end points remains an area in need of further investigation.

### **Implications for clinical practice**

There is currently insufficient evidence to support the use of ultrasound, low-level laser, and electromagnetic therapy in treating venous ulcers. Further well-designed trials are needed before these modalities should be widely adopted (Level I).

## **Intermittent pneumatic compression**

### **Benefits**

Intermittent pneumatic compression has been used for a number of indications. Since the underlying cause of venous ulceration is postulated to involve deficient blood return in the calf muscle pump, it has been suggested that intermittent pneumatic compression could improve the healing rates of venous ulcers by improving venous return (i.e., acting as a form of lower limb compression).

Intermittent pneumatic compression for the treatment of venous ulcers has been the subject of a Cochrane collaborative review [55]. This review evaluated seven randomized controlled trials of intermittent pneumatic compression for the treatment of venous ulcers. One trial of 45 patients compared intermittent pneumatic compression plus standard limb compression with standard limb compression alone and found a significant benefit in the intermittent pneumatic compression plus standard compression group, with a relative risk of healing of 11.4 (95% CI, 1.6–82). Three other small trials (122 people altogether) failed to find a significant benefit of intermittent pneumatic compression plus standard compression over standard compression alone. Notably, the duration of therapy with intermittent pneumatic compression in these trials varied considerably. Moreover, the study end points differed substantially. One small study compared intermittent pneumatic compression alone (i.e., without standard compression) with standard compression, and failed to show a significant difference between the groups.

### **Complications**

There are few real complications with intermittent pneumatic compression; as long as the equipment is properly set up, patients would not be expected to suffer any injuries.

### **Comment**

Intermittent pneumatic compression may be beneficial as an adjunct to standard limb compression, but this has yet to be conclusively demonstrated. One of the larger studies noted in the Cochrane review did demonstrate a benefit, but the standard compression used was graduated compression stockings – in contrast to the Unna boot used in another study, which failed to show a significant difference in the proportion of ulcers healed after 6 months. Of note, both studies demonstrated an increase in the actual rate of healing, suggesting that the different study end points (3 vs 6 months) may have played a role in the differing results.

The size and method of use of the equipment requires the patient to remain in a single place for the duration of therapy. The equipment is also costly.

### **Implications for clinical practice**

Intermittent pneumatic compression may increase the rate of wound healing for patients already treated with standard compression. In addition, delivering the intermittent pneumatic compression in a rapid manner by inflating and deflating the device more quickly results in better ulcer healing. However, further study is needed to discover the definitive effects of this device on healing (Level I).

## **What therapies are effective in reducing the risk of recurrence of venous leg ulcers?**

### **Compression**

#### **Benefits**

Compression therapy has been demonstrated to be an effective therapy for increasing the likelihood that a patient with venous ulcers will heal after 12–24 weeks. Since many venous ulcer patients have recurrent ulcers even after they have successfully healed, a pressing question remains as to whether continued compression after wound healing could reduce the likelihood of recurrent venous ulcer formation.

A Cochrane collaborative review has evaluated compression as a treatment for preventing the recurrence of venous ulcers [56]. This systematic review found one study (153 patients) directly comparing the incidence of recurrent ulcers in patients who did and did not use compression. This study found that compression significantly reduced ulcer recurrence at 6 months with a relative risk reduction of 54% (95% CI, 24–72%). Three other studies were included in the systematic review. One study compared medium-compression and high-compression stockings and did not find a significant difference between the recurrence rates in these two groups. Another study assessed ulcer recurrence at 3-year follow-up and found that high-compression hosiery reduced recurrence compared with moderate compression. The final study compared two different types of medium-compression stocking and did not find any significant differences between the two groups. The studies did in fact examine differences in recurrence rates between patients who were and were not compliant with compression stockings, and this demonstrated that patients who were noncompliant with compression were more likely to have recurrent ulcerations [56,57].

#### **Complications**

Complication rates are not usually noted in trials, partly because compression therapy is generally benign. Inexpertly applied high compression could lead to soft-tissue damage, the development of additional wounds, and potentially amputation, although the chance of this occurring is remote.

### Comment

One study has shown that compression reduces the risk of recurrent venous ulceration. Two studies that compared different types of compression found that noncompliant patients had a higher rate of recurrence than those who were compliant with any type of compression regimen [57]. While these data may seem to suggest that ulcers may recur in patients who do not use compression, there are other confounding factors that need to be addressed before this conclusion can be drawn. For example, noncompliant patients may be more or less likely to have serious wounds or to comply with other elements of wound care, including nutrition and avoiding trauma.

The findings of a recent Cochrane review that showed compression significantly reducing ulcer recurrence at 6 months with a relative risk reduction of 54% – coupled with the implications of the noncompliant patients' increased rate of recurrence from earlier trials and the biological plausibility of this therapy – mean that compression is likely to reduce the risk of recurrence of venous leg ulcers. Finally, compression therapy to prevent recurrence is considered by most wound-care experts to be "standard therapy." It might not be ethically justified to conduct a trial comparing limb compression with no limb compression for prevention of recurrent ulceration.

### Implications for clinical practice

Compression appears to reduce the risk of recurrent venous ulceration, and should be recommended for all patients with a history of venous leg ulcers as long as they do not have any other conditions that would make this therapy potentially harmful (e.g., arterial disease) (Level I).

### Surgery

#### Benefits

In the last decade, there have been several randomized controlled trials carried out to assess the efficacies of superficial venous surgery and conservative compression therapy with regard to the healing and recurrence of venous ulcers [58–62]. The Effect of Surgery and Compression on Healing and Recurrence (ESCHAR) study and a study by van Gent *et al.* were the largest studies with over a hundred patients or more in each arm [60–62]. The ESCHAR study was a multicenter randomized controlled study that evaluated compression therapy with superficial venous surgery in comparison with compression therapy alone. The long-term data from the ESCHAR study demonstrated after 4 years an improved recurrence rate (31%) after surgery with compression, over compression therapy alone (56%) ( $P < 0.01$ ), but no improvement in healing rate [62]. The van Gent *et al.* study primarily assessed subfascial endoscopic perforator surgery (SEPS) with saphenous surgery as an adjunct and found healing and recurrence rates to be similar, but ulcer-free rates were statistically improved in favor of surgery. In four other studies, SEPS to correct perforator disease was looked at and found to show positive results in ulcer healing and preventing recurrence [63–66]. A recent systematic review found that the role of superficial venous surgery in the management of venous ulcers was associated with similar rates of ulcer healing compared with compression alone, but with less recurrence [67].

Many patients with a venous leg ulcer are elderly and frail and do not want, or are not fit for, venous surgery under general anesthesia. A number of studies have looked at ultrasound-guided foam sclerotherapy as a treatment for venous ulcers [68–73]. This

can be done as an outpatient in the office and works by occluding superficial incompetent veins, thereby removing its contribution to the chronic venous hypertension which is thought to play a role in venous ulceration. It is thought that sclerosing superficial veins may be similar to surgical superficial vein ablation, which when used with an adequate compression system may improve ulcer treatment. The studies at this point are mostly small and observational, so must be interpreted with caution.

### Complications

Almost all venous surgery is performed under general anesthesia, which comes with risks. There is a potential risk of stroke with ultrasound-guided foam sclerotherapy.

### Comment

Current evidence supports the practice of venous surgery to decrease ulcer recurrence. Many patients are not surgical candidates. This makes other options such as ultrasound-guided foam sclerotherapy more attractive, but more studies are needed on this modality.

### Implications for clinical practice

In order to justify venous surgery, it must offer considerable benefits over compression therapy alone in terms of healing rate, recurrence, pain relief, and cost and quality of life to outweigh the potential risks of anesthesia and invasive intervention. The number of potential candidates suitable for venous surgery from the population with venous ulceration is reported to range from less than half to around a third [58,61] (Level I).

### Key points

- Limb compression is the mainstay of therapy for venous leg ulcers, and several studies have shown that compression offers a clear benefit over no compression.
- Pentoxifylline and the flavonoid fraction of *Rutaceae aurantiae* as an adjuvant therapy to limb compression have been shown to increase the likelihood of healing.
- Skin equivalents as an adjuvant therapy to limb compression are associated with an increased likelihood of healing.
- The use of long-term limb compression therapy for those with a healed venous leg ulcer is associated with a decreased rate of recurrence, although poor compliance does compromise the effectiveness of this treatment.

### Why a chapter on “everything else”?

Any textbook purporting to guide clinical dermatological practice that fails to cover the majority of skin diseases is open to major criticism. Yet, as Naldi points out in Chapter 1, around 1000–2000 skin conditions have been described to date, and trying to cover them all in just one textbook and in sufficient detail is challenging. In the second edition of this textbook, we aspired to cover as many of the common or important conditions as possible – the words “common” or “important” being defined empirically by the editors on the basis of epidemiological studies and clinical practice around the world. Although we have included more conditions, such as molluscum contagiosum, as discrete chapters in this edition of the textbook, the question remains, what happens to the remaining 1900 or so less common or ignored skin diseases? Many of these other skin conditions may be rare in relative terms, yet collectively they make up a significant component of the dermatologist’s workload, and diagnosing and managing them may take up a disproportionate amount of time relative to the everyday conditions seen in clinical practice. Previous research on the use of Internet resources in dermatology suggests that many hits/requests are concerned with less common skin diseases [1]. From a patient’s perspective, being told that you have a rare skin disease is of little consolation, especially if your doctor knows little about it and you need to find out about effective treatments. So, there is a clear case for including as many less common skin disorders as possible in a book such as this.

In the second edition of this textbook we attempted to “find a home” for all of the randomized controlled trials (RCTs) that we could find on less common skin diseases that were not included in the other disease-based chapters. We included over 70 RCTs on less common conditions, and they are still summarized and available as Web Table 74.1 accompanying this book. One thing we learned from that exercise is that you should never assume that there is no good evidence out there just because a skin disease is rare, as we found informative RCTs on a variety of less common disorders, including perniosis, erythromelalgia, nostalgia parasthetica, and Jessner’s lymphocytic infiltrate. The lesson, therefore, is always to search for high-quality evidence using the methods outlined in Chapter 6.

We have not persisted with the same approach of trying to capture all relevant remaining RCTs for this edition as our initial searches indicated that we would need to include at least another 150 RCTs. The explosion of RCTs over the last 5 years in dermatology is potentially positive, but it has meant that trying to include and summarize them all would take up a book in itself, and its utility to the busy clinician would be limited. Instead, therefore, and true to the spirit of the hierarchy of evidence developed in Chapter 7, we have tried to identify systematic reviews of interventions for those skin diseases not covered in the preceding chapters.

### The importance of mapping all systematic reviews

As well as the requirement to ensure at least some degree of coverage for less common skin diseases in this book, there is a need to point health-care providers and patients to the most reliable sources of evidence; that is, systematic reviews of RCTs. Mapping all of the published systematic reviews for a given disease has been done by our team for atopic eczema and acne, and such maps are available in the public domain from the Centre of Evidence-Based dermatology website <http://www.nottingham.ac.uk/scs/divisions/evidencebaseddermatology/resources/index.aspx>. The Cochrane Library is the best source of high-quality systematic reviews in skin diseases [2], although non-Cochrane systematic reviews in dermatology have expanded rapidly [3]. Some of the systematic reviews we have included in this chapter are better than others in terms of quality and scope, but they are nevertheless presented in Web Table 74.1 for users to know (i) that a systematic review has been undertaken on the skin condition in question, (ii) what the review attempted to do, (iii) what the reviewers concluded, and (iv) our own comments on the review.

The search was undertaken in Medline using the skin condition terms listed in Web Table 74.2 and the SIGN filter for systematic review (SR) searching. The search identified keyword searches in the title only, no MeSH terms, no truncation, and no plurals. Of the 92 references identified from the year 2000 to the search date of September 8, 2012, 16 were published in the last 5 years and have been included in this chapter. The data extraction sheet was piloted

by undertaking dual extraction for a small proportion of papers to ensure consistent methodology and completeness of extraction.

## Comment

The quality of the systematic reviews in the table varied from high-quality reviews to reviews with very limited searching, lack of critical appraisal of included studies, and lack of appropriate quantitative data. Nevertheless, the topics of the reviews alone indicate where there is investigator interest in trying to move the field forward, and these include aphthous ulceration (two reviews), chronic foot ulcers (seven), hidradenitis suppurativa (one), and epidermolysis bullosa, lichen sclerosus, morphoea, and pityriasis rosea. None of these topics can be really considered rare skin diseases, and some such as diabetic foot ulcers result in a large amount of population morbidity and health-care costs. Whilst the clinical messages emanating from these systematic reviews (such as erythromycin might be useful for speeding up clearance of pityriasis rosea) are limited and tentative, the main pattern to emerge from the reviews is that studies have been done, but they are too small and poorly reported. They thus provide a strong wake-up call to the dermatology com-

munity to improve the quality of clinical trials, and to always start a trial by seeing what has been done already so that the same old mistakes and designs are not repeated time and time again with increasing confidence.

## The future of evidence-based dermatology

Luigi Naldi, editor

## Where do we go from here?

Hywel C. Williams

Centre of Evidence-Based Dermatology, University of Nottingham, Nottingham, UK

### What is the point of discussing evidence-based dermatology?

The idea that doctors should base their treatment decisions on good evidence seems such an obvious notion that it might be taken for granted. Who can really be opposed to the central tenet of evidence-based medicine (EBM) – that of using the best evidence wisely [1]? It is not as if there is one group of dermatologists “over there” practicing evidence-based dermatology (EBD) and another group “over here” who choose not to (Figure 75.1). If the practice of EBD goes without saying, what is point of discussing and promoting EBD?

Medicine is advancing very rapidly, creating major changes in the way dermatologists treat patients. Although there is a clinical need to keep up to date with the exponential growth of such new external evidence, dermatologists frequently fail to keep up if they only rely on an occasional flick through the main dermatology journals or a visit from a pharmaceutical representative. Such a policy leads to a deterioration of knowledge with time. Attempts to

overcome this deficiency by attending clinical education programs have been shown to fail to improve our performance, whereas the practice of EBM has been shown to keep its practitioners up to date [2]. New skills need to be learnt on how to search electronic bibliographic databases efficiently and how to critically appraise the different types of study, as outlined in the “toolbox” section of this book (Part II). Yet time for such activities is very limited in a busy clinical schedule. Dermatologists cannot be expected to read and appraise every new randomized controlled trial published in dermatology, especially as reliance on one early randomized controlled trial can be hazardous, even when published in a prestigious journal [3,4]. Instead, high-quality systematic reviews that have searched for all relevant data are needed to update dermatologists on current best treatments.

It is important to point out that the acquisition of new information technology skills does not mean that they replace the attributes of being a good doctor, such as history-taking and examination skills, often described as the “art” of medicine [5]. As the original definition of EBD developed in Chapter 2 implies, the practice of EBM is an integration of knowledge management skills with clinical skills. The aim is to create an emergent, knowledgeable, up-to-date, skillful, caring, and efficient doctor.

**Figure 75.1** It's not as if there are two distinct groups of dermatologists separated by a brick wall: one evidence based and the other not. All dermatologists practice EBD to some degree. But like learning how to perform skin surgery, learning the basics of formulating questions, searching, critical appraisal, and interpretations are skills that have to be acquired and practiced.

### What exactly are the advantages of evidence-based dermatology?

#### Being systematic, explicit, and up to date

At the top of the evidence hierarchy tree discussed in Chapter 7 stands the systematic review. Systematic reviews of randomized clinical trials (RCTs) developed after it was realized that traditional reviews were done in quite arbitrary ways [6]. Traditional expert reviews are fine for raising issues for discussion and debate, but they are much less suitable for summarizing treatment effects. The unsystematic approach used in such traditional reviews often means that they are more prone to bias and influence from hidden agendas [6]. Many have written “traditional” review articles in the past containing a biased selection of citations to support predetermined views, and the author confesses to having used the “file drawer” method to search for articles in one of his reviews of atopic eczema in 1995 (Figure 75.2) [7].

**Figure 75.2** The good old “file drawer” method for locating studies is still the method used and preferred by some authors of traditional “expert” reviews.

Systematic reviews, such as those produced by The Cochrane Collaboration, summarize accurate, up-to-date, high-quality external evidence of the benefits and harms of interventions for treating and preventing human disease [2]. Cochrane reviewers use and refer to a published protocol to describe precisely how they will search, appraise, and synthesize data concerning a specific clinical question, as described in Chapter 8. Such an explicit structure and methodology means that another researcher could replicate the review if necessary, even down to the level of planned subgroup analysis. Like any good randomized controlled trial, the protocol of a good systematic review will be published before the main review is done in order to prevent being driven by data discovered when putting the studies together. For example, it is easy within the context of a systematic review to end up colluding with seven RCTs that have measured a clinically dubious outcome measure by providing a meta-analysis of such data, instead of pointing out that none of the studies had measured what is really important to patients according to a prespecified primary outcome published in a protocol. A recent clinical trial of levamisole measured serum tumor necrosis factor levels as the sole outcome in patients with oral lichen planus rather than symptom control – when did you last see a serum tumor necrosis factor walk into your clinic [8]? An international database of systematic reviews protocols has been set up called PROSPERO with the aim of providing a “one-stop shop” for prospectively registering all systematic reviews in health and social care <http://www.crd.york.ac.uk/Prospéro/>.

### Keeping up to date and increasing precision

Evidence from cardiovascular medicine has shown that doctors have failed to use effective treatments, such as intravenous streptokinase, for acute myocardial infarction even when there was overwhelming evidence for their effectiveness [9]. Conversely, they continued to recommend medicines such as intravenous lidocaine for post-infarction arrhythmias long after the evidence suggested that they were ineffective or even harmful [10]. With over 280 specialist dermatology journals (<http://skin.cochrane.org/>), it has become increasingly difficult for the dermatologist to keep up with the literature [11]. Systematic reviews such as those supported by the Cochrane Skin Group that track down all possible published and unpublished studies are needed to keep dermatologists and other health-care professionals up to date [12]. Cochrane Skin

**Figure 75.3** Research users must overcome the slavish obsession for dividing the results of all clinical trials into those that are statistically significant at the 5% level and those that are not, and instead use confidence intervals to estimate a range of likely effects.

Group reviews have been shown to be of higher quality than non-Cochrane reviews dealing with dermatology [13], and they are also updated as new evidence and criticisms become available. Over 200 systematic reviews now exist on the Cochrane Library that are relevant to skin disease (<http://www.thecochranelibrary.com/view/0/index.html>). Given that systematic reviews have become a rapidly increasing publication type in dermatology [14], some groups have produced maps of systematic reviews (Cochrane and non-Cochrane) relevant to a particular topic such as eczema in the public domain, so that users do not have to waste time searching for such reviews themselves [15].

Systematic reviews can also reduce uncertainty and confusion created by the apparently conflicting results of several small inconclusive studies by combining their results – provided they are sufficiently similar. This may overcome the common tendency to divide all clinical trials into those that are significant at the arbitrary 5% level and those that are not (Figure 75.3), instead of pooling studies that are sufficiently alike in terms of patients, interventions, and outcomes into summary estimates that indicate a range of plausible treatment effects by means of confidence intervals. Studies that reach the “magic”  $P < 0.05$  significance level are commonly claimed as being “positive” and those that fail to reach that level are often considered “negative,” whereas in reality many of the latter trials are far too small to detect even quite large changes [16]. Instead of concluding that such studies are “conflicting,” a meta-analysis performed within the context of a carefully conducted systematic review may show that they are all compatible with a clear overall treatment benefit. The Cochrane Collaboration logo shows a good example of this (Figure 75.4).

### Minimizing bias and identifying research gaps

EBD is very much concerned with reducing bias. Systematic reviews are powerful tools for minimizing bias, because they use explicit methods and because they seek to include all relevant studies rather than studies selected on the basis of their results or how easy they

**Figure 75.4** The Cochrane Collaboration logo depicts a systematic review of seven placebo-controlled trials evaluating the efficacy of a short course of oral corticosteroids for women in premature labor to prevent fetal death. Each horizontal line represents a single RCT; the shorter the line, the more certain are the results. If an RCT touches the vertical line, it means that particular trial found no clear evidence of treatment benefit. The diamond at the bottom represents the combined results, and its position to the left of the vertical line of no treatment difference indicates that the treatment was clearly beneficial in reducing premature infant mortality by 30–50%.

The first of these RCTs was done in 1972. The figure depicts what would have been revealed had a systematic review of the available evidence been done a decade later. By 1991, another seven RCTs had been done. Because no systematic review of these studies had been produced until 1989, most obstetricians had not realized that the treatment was so effective, but instead interpreted each individual study as “conflicting.” As a result, tens of thousands of premature babies around the world have probably died or suffered unnecessarily. This is an example of the human costs of failing to perform an up-to-date systematic review of apparently “conflicting” studies.

(Source: the Cochrane Collaboration.)

are to find. When assessing an intervention for skin disease, the prospective protocol provides an opportunity to state which participants should ideally be studied, which comparators are appropriate, and which outcomes would make a difference clinically and at what time point. Such a “bottom-up” and nonreductionist approach also provides the opportunity of consulting users or consumers (people with a condition, or their carers) to ensure that the perspective of the review and the outcome measures are appropriate. The beneficial role of such service-user involvement is extolled in Chapter 3. Lay summaries are included in Cochrane reviews as the language used by clinicians and researchers is sometimes confusing to consumers (Figure 75.5). Specifying analysis plans in protocols also helps minimize the problem of data-driven reviews that amplify features of studies that may interest the pharmaceutical industry more than patients or health-care professionals. Even for rare skin diseases, producing a systematic review that finds no reliable evidence to inform practice may still be useful, in that it reassures practitioners that they are not missing some important new development [17]. Systematic reviews also have an important role to play in highlighting possible research gaps for future study [18–20], and many funding bodies now will not commit to funding an RCT without a systematic review being done first. It should be noted that, like any other study design, there are good and bad systematic reviews, and even the better ones have room for improvement [21].

**Figure 75.5** Working with patients and carers requires a clear explanation of terms used in studies. For example, the phrase “subjects were broken down by age and sex” is not immediately clear to those working outside of research.

The basic unit of analysis in most systematic reviews is the RCT. As pointed out in Chapter 9, like any study design, RCTs can also be done badly and used in the wrong situations [22,23]. Nevertheless, the RCT remains one of the strongest designs in modern medicine for assessing treatment efficacy, because of its potential to minimize bias [22]. As Bigby points out in his essay on “Snake oil for the 21st century,” studies of inferior design, such as case series, have many times led to overly optimistic claims of treatment efficacy in dermatology that were not borne out by subsequent RCTs [24].

### Influencing the agenda of future dermatology trials

Perhaps the most important and subtle advantage of EBD is its propensity to help change the RCT agenda. It is quite clear from a systematic review of 272 RCTs in atopic eczema that most trials have reflected the agenda of the drug industry in order to license a particular “me-too” product, and that many questions that are important to clinicians and patients remain unanswered [19]. Similar conclusions have been voiced in a review of all RCTs conducted in the field of psoriasis by the European Dermato-Epidemiology Network [25]. Many of the outcome measures used in these trials are clinical scoring systems that may show up minor differences in disease scores in the short term, yet their clinical significance in practice is often obscure, especially in chronic diseases where disease remission and quality of life may be more important. EBD is thus a key instrument in informing the need for comparative effectiveness research using pragmatic clinical trial designs and active comparators when trying to answer questions about which treatment is best [26].

### What are the potential limitations of evidence-based dermatology?

#### The threat of reductionism

Meta-analysis, which refers to the statistical pooling of results drawn from several studies, is prone to dangerous reductionism if used to add studies together which it is not sensible to combine in the first place [27,28]. Thus, before contemplating playing with any statistical techniques, it may be wise to consider not combining

studies of childhood atopic dermatitis with those dealing exclusively with adult atopic dermatitis, as they may differ in terms of etiology, treatment responsiveness, and propensity for adverse effects. It may also be sensible not to combine studies of atopic eczema that evaluate one sort of dietary exclusion with another. It may not make any sense to pool a clinically obscure outcome measure, such as a “doctor-assessed itch,” simply because it was the only outcome that was common to all trials [19]. Meta-analyses are only as good as the data from the individual studies that make up such analyses, and great care needs to be taken to avoid adding together things that should not be combined, especially when the statistical output with lots of numbers and decimal places may give rise to a spurious air of precision to those less experienced in assessing the quality of such analyses. It is for this reason that meta-analyses should always be performed within the context of a systematic review [29].

The involvement of users is another important aspect that may protect against reductionism – for example, in the choice of outcomes. Another criticism of meta-analyses is that, as more and more data are pooled and aggregated, it becomes more difficult to apply such “average” summary measures to individual patients – in other words, EBM applies to populations and not to individuals [30]. This is a somewhat specious argument, given that extrapolation from groups to individuals is a paradox that is fundamental to all scientific studies on groups of people. The paradox of groups and individuals is also applicable to “clinical experience,” which by definition relies on recall of aggregated experiences with groups of patients. It can also be argued that combining several studies containing a broad range of people with different ethnic backgrounds, sex, and co-morbidities actually *increases* external validity to a wider and more typical group of patients, rather than relying on a single trial that describes a narrow range of trial participants.

Reductionism can also occur if EBD practitioners become too preoccupied with the critical appraisal of research without considering the many human factors that are central to the successful practice of EBD as introduced in Chapter 2. Hajjaj *et al.* produce a useful summary of nonclinical influences beyond diagnosis and disease severity that may determine why a gap often exists between practice guidelines and clinical practice [31]. Eaglstein also refers to such a research-practice gap and suggests that a number of physician cognition patterns may be responsible, such as bias against the beneficial, omission bias, multiple alternative bias, and preference for indirect harms [32].

## Cheating

As with any research methodology, it is possible for those with a vested interest to twist the methods and conclusions of a systematic review to their own advantage [33]. Thus, one could conveniently fail to include one crucial study that contradicted the results one wanted to show, or if the study is declared within the review one could find a weak excuse to exclude it post hoc. Because many trials never see the light of day in terms of publication, or are held as “data on file” or just held back by some pharmaceutical companies [34], it is possible for a review to include or exclude such additional unpublished data in a way that favors the product [35]. As with any written document assessing drug treatments, there is plenty of scope for undue emphasis on positive effects and lack of discussion of relevant adverse events. Readers need to develop a “good nose” for what constitutes a good systematic review and clinical trial; some pointers are given in Chapters 8 and 9. This includes starting with a peep at the acknowledgments to see who sponsored the

review or study and assess possible conflicts of interest [36,37] – if, in fact, sponsorship has been declared [38,39].

## Overemphasis on randomized clinical trials

Whilst RCTs may be the most robust study design for minimizing bias in conventional evaluation of the effectiveness of interventions for skin diseases, they have their limitations [40]. In some circumstances, it may be impossible or unethical to perform an RCT. For example, it is unlikely that mothers will agree to be randomized to breastfeeding or bottle-feeding to see whether either prevents atopic eczema. Similarly, it would be impractical to randomize medical students to one form of education and others to another within the same class, because they would not be blinded to the interventions, and there might be considerable “contamination” of the intervention from one group as students talk together. Just because a study is an RCT does not mean that it is a good RCT, and attention to quality and relevance is important, rather than just blindly following the concept of the hierarchy of evidence. Rare but serious events, which are extremely important when evaluating the pros and cons of a new treatment, are not well characterized within RCTs, but instead require other approaches such as case reports, case-control studies, and wide-scale pharmaceutical surveillance methods, as Naldi points out in Chapter 10. Frequently, there is asymmetry in the way that systematic reviews devote a lot of space to treatment efficacy and less or none to issues such as potentially serious side effects [41].

The concept of only using RCTs as the basic building blocks of evidence for systematic reviews has been criticized because it implies that all other evidence that contributes to our understanding of treatment efficacy, such as case series, case reports, and “clinical experience,” are not valid [42]. This is clearly inappropriate. Ideally, the totality of evidence should be considered when conducting a systematic review, so that evidence from observational studies can contribute to the conclusions from RCTs. Approaches such as hierarchical modeling, likelihood estimations, and Bayesian statistics have been used in attempts to address these gaps. It is likely that the concept of a good informative study design is more of a continuum representing the risk of bias, rather than a dichotomy of “good” (i.e., RCTs) and “bad” (e.g., a large case series). This continuum needs to be tempered by the added but crucial dimension of study quality.

Another potential drawback of only incorporating RCTs into systematic reviews is that older traditional therapies, such as curettage and electrocautery for actinic keratosis, which were rarely assessed to the same RCT standards as modern therapies when first introduced but which have stood the test of time, will often lose out to newer industry-funded and more expensive treatment simply because they fail to pass the required level of evidence [43]. Lack of evidence of a well-established treatment does not necessarily imply that such treatments are inferior, although it is always desirable to test such treatments as active comparators when new treatments are introduced, as has recently been done with topical imiquimod cream against standard excisional surgery for low-risk basal cell carcinoma [44].

There are challenges, therefore, for future systematic reviewers to find ways of incorporating informative data from nonrandomized studies, and methodology groups addressing such issues exist within the Cochrane Collaboration. In the meantime, it is best to walk before running, by adhering to the RCT as the basic study design for assessing treatment efficacy in dermatology, at least until better methodological approaches have evolved.

## Reviews always end with the phrase “insufficient evidence”

A common criticism of Cochrane skin reviews by dermatology trainees is that they always end up with the same conclusion: that there is “insufficient evidence” to inform current practice. Whilst this may be true for some reviews, a glance at the reviews in the Cochrane Database of Systematic Reviews shows that at least 40% of those relevant to a practicing dermatologist make specific and clear recommendations for therapy [45]. Even “null reviews” that do not find any good evidence to make specific treatment recommendations have their uses. Thus, a systematic review evaluating the evidence for antistreptococcal treatments for guttate psoriasis found no reliable evidence, despite confident textbook recommendations in favor of such a treatment approach [20]. Not only does such a review identify a major gap needing research, but it also reassures doctors and their patients that they are not missing some important study. It empowers doctors to feel more confident in relying on other levels of evidence, such as case series and empirical reasoning based on mechanism, until better studies are done. It also empowers patients with guttate psoriasis, by allowing them to challenge doctors who insist that they must take prolonged courses of antibiotics or who threaten to take out their tonsils (Figure 75.6).

## Evidence-based paralysis

Absence of RCT evidence does not mean that dermatologists should become paralyzed into doing nothing – so-called therapeutic nihilism [46]. Failure to find any RCTs for the treatment of acne agminata, for instance, does not mean that patients should be told to go away because there is no treatment. It is possible that a well-conducted case series exists, or a convincing case report, or simply the sharing of anecdotal evidence from a senior colleague. All forms of evidence are entirely appropriate to use in the absence of better sources. It is just that, for many years, the evidence hierarchy has been inverted in everyday dermatology practice: starting with muddling along and experimenting on individual patients on empirical grounds, or asking a colleague, or referring to an out-of-date textbook.

**Figure 75.6** One Cochrane systematic review found no good evidence to support the use of antistreptococcal interventions (prolonged antibiotics or tonsillectomy) for treating guttate psoriasis. Sometimes such a “negative” systematic review can be useful, in that it can empower patients to question doctors on the evidential basis for their treatment decisions.

## Evidence not up to date and poor primary data

Whilst it is the aspiration of the Cochrane Collaboration to update all of its systematic reviews periodically as new primary data emerge, the reality is that such updating activity is incomplete, which is not surprising given that it is largely a voluntary activity. Keeping right up to date remains a challenge, and those using systematic reviews often need to undertake additional electronic searches to make sure that no new key studies have emerged since the reviews as a result.

Although the methods of undertaking systematic reviews have become increasingly sophisticated, the raw materials of reliable data are often lacking [47], and it will take some time before the field of dermatology recognizes the importance of good trial design, prospective trial and systematic review registration, and complete reporting. Some promising signs have emerged [48], but it is too little and too late for many research users. Reducing future research wastage by encouraging clinicians and patients to prioritize research questions [49,50], ensuring good study designs that minimize bias, and making sure that all results are published and that they are published fully and honestly and interpreted in the context of other relevant research are all needed urgently if medical and dermatological research is to hold any credibility and trust with the patients who volunteer to participate in such research.

## Progress and future prospects for evidence-based dermatology

The potential limitations of EBD are diverse and only partly justified. Some (such as inadequate coverage) are a function of time, while some (such as reductionism, a refusal to consider non-RCT evidence, and cheating) belong predominantly to those conducting and publishing systematic reviews. Other aspects, such as evidence-based paralysis or failure to use available evidence, are a misunderstanding or form of neglect that belongs to those using the evidence. Many of the commonly cited criticisms, such as “all skin reviews are negative” or “EBD ignores patient values,” fall down when challenged by objective data and when the original tenets of evidence-based practice are revisited.

## Mapping priorities, collaborating and thinking globally

Too much research has been conducted in isolation at the whim of academics and industry leaders without any form of joined-up thinking. Liberati, founder of the Italian Cochrane Centre, who eventually succumbed to myeloma, found it so frustrating to witness the “the butterfly behaviour of researchers, moving onto the next flower well before the previous one has been fully exploited” [51]. More emphasis should be placed on mapping the entire evidence base of ongoing reviews and clinical trials in each major dermatological disease, as is being done for atopic eczema with maps of systematic reviews [15] and the GREAT database (Global Resource of Eczema Trials) [52]. Undertaking network meta-analyses of all available studies permits key comparisons of interventions that might have been deliberately avoided in primary research, as well as allowing a glimpse of what has been done and where more research needs to be done [53]. Working with patient groups in priority-setting exercises is also a good place to start before rushing off to do more research that may turn out to be of little clinical value or, worse still, duplicates existing or ongoing research [50]. Collaboration outside of traditional institutional

territories is essential to answer the big clinical trial questions in dermatology research, especially for less common skin disorders. Thus, the UK Dermatology Clinical Trials Network has gathered the help of 50 recruiting centers in order to determine whether oral tetracyclines have a useful role in the treatment of bullous pemphigoid [54] or which is the most effective treatment of pyoderma gangrenosum [55]. Other countries have shown interest in developing similar country-specific or disease-specific networks, and a website has been created to provide a focus for such international efforts: <http://www.ifdctn.org/ifdctn/index.aspx>. Such networks are also important vehicles in the “democratization of research” into the coal face of the clinical community who are well placed to take more ownership in choosing the right questions, delivering the research and changing their practice on the basis of the study results [56].

### So, is it all just another fashion that will come and go?

For some, the whole concept of EBD might seem like just another new management-driven fad that will come and go like others [24]. Perhaps it is the human factor of shame in admitting that some of our previous treatment beliefs might be wrong that prevents progress – the “elephant in the front room” that doctors keep bumping into without seeing [57]. Yet what is the alternative to EBD? Is it anecdote-based medicine (“I once treated a patient with such and such with remarkable effect . . .”), entropy-based medicine (“let’s try this cream today. . .”), arrogance-based medicine (“I know best”), or propaganda-based dermatology driven by powerful cartels with vested interests? It is hard to believe that any caring dermatologist would not wish to base their treatments on the best external evidence. Two studies have already shown that dermatologists use as much high-quality external evidence to inform their treatment decisions as other specialists do [58,59]. Since the last edition of this book, considerable progress has been made to incorporate EBM into continual professional development and clinical practice. Major dermatology journals, including the *Journal of Investigative Dermatology*, *Archives of Dermatology* (now *JAMA Dermatology*), the *British Journal of Dermatology*, the *Journal of the American Academy of Dermatology*, and the *Indian Journal of Dermatology*, have been forthright in their insistence on prospective trial registration and adoption of good trial reporting guidance from the Consolidated Standards of Reporting Trials (CONSORT) statement for improving the reporting of trials. The *Journal of the American Academy of Dermatology* now runs a section on summaries of Cochrane reviews [60], and the *British Journal of Dermatology* now promotes submissions of critically appraised topics rather than a sea of case reports [61]. Taboo issues, such as conflict of interest, are now being openly discussed at dermatology journals and meetings, with appropriate declarations during presentations [36]. EBM principles form part of many teaching curricula in dermatology, and specific courses that use dermatological examples are appearing at major dermatology meetings and centers (<http://www.bees.org.uk/courses/about/>). Dermatology is no longer a backwater for EBM, although it still has a long way to go. One of the most difficult challenges common to all EBM is how to ensure that the findings of well-conducted studies are incorporated into practice [62].

It is reasonable at this point to ask, “What is the evidence for EBD?” An entire theme issue of the *British Medical Journal* was dedicated to this topic in 2004, although it came up with more questions than answers, mainly due to the methodological difficul-

ties in linking EBM teaching to clinical outcomes [63]. In some senses, it is a tautological question, as it implies that there is a group of doctors who are evidence based and another group who are not, as pointed out at the start of this chapter (Figure 75.1) – whereas the reality is that all belong to a dynamic and complex continuum. Such a continuum makes the evaluation of “EBM” as an intervention in its own right almost impossible to assess by means of an RCT. In-depth discussions on the epistemology and ethical issues posed by the name and concept of EBM can be found elsewhere [27,46,47,64,65].

Trying to divide physicians into those who are evidence based and those who are not is a form of binary thought disorder and not an accurate reflection of real life. Like Molière’s bourgeois gentilhomme, who, after 40 years, discovered that he had been speaking prose without realizing it, many dermatologists have been practicing, and will continue to practice, high-quality EBD. Yet all health-care professionals need to learn new skills in searching, appraising, and translating the evidence. That part is now up to you.

### Acknowledgments

I would like to thank Mr Jack Tweed, consumer volunteer working with the Cochrane Skin Group, for highlighting the inappropriate phrase “subjects were broken down by age and sex” which inspired the author to draw the cartoon in Figure 75.5.
